

Encyclopedia of Cell Biology

EDITORS IN CHIEF

Ralph A. Bradshaw and Philip D. Stahl

How to go to your page

This eBook contains Four Volumes. It contains an Index at the end of each volume.

The front matter and content of each book have their own page numbering scheme, consisting of a volume number and a page number, separated by a Colon.

For example, to go to page 18 of Volume 1, type "V1:18" in the "page #" box at the top of the screen and click "Go."

To go to page "123" of Volume 2, type "V2:123" or to go to page "vii" of Volume 3, type "V3:vii"and so forth.

Please refer to the eTOC for further clarification.

DEDICATION

Dedicated to Anthony James (Tony) Pawson (1952–2013), in recognition of his outstanding contributions to cell biology and our understanding of intracellular communication mechanisms...

EDITORS-IN-CHIEF

Ralph A Bradshaw is Professor Emeritus in the Department of Physiology and Biophysics at the University of California, Irvine. Prior to that he was on the faculty of the Department of Biological Chemistry, Washington University School of Medicine in St. Louis, MO and was Professor and Chair of the Department of Biological Chemistry at University of California, Irvine. From 2006 to 2015, he was a member of the Mass Spectrometry Facility and Professor of Pharmaceutical Chemistry at the University of California, San Francisco. He holds degrees from Colby College and Duke University and was a post-doctoral fellow at Indiana University and the University of Washington. He has served as president of FASEB, was the founding president of the Protein Society and was the treasurer of the American Society for Biochemistry and Molecular Biology. His research has focused on protein chemistry and proteomics, with emphasis on the structure and function of growth factors and their receptors, particularly nerve growth factor and fibroblast growth factor, and the involvement of receptor tyrosine kinases in cell signaling. He has also studied the role of proteolytic processing and N-terminal modification in protein stability and turnover.

Philip D Stahl is E. Mallinckrodt Jr. Professor Emeritus at Washington University School of Medicine in St. Louis, MO. He was educated at West Virginia University with post-doctoral work at Vanderbilt University. He served as Head of the Department of Cell Biology and Physiology and Director of the Division of Biology and Biomedical Sciences at Washington University. He has been the recipient of many awards including a MERIT award from the NIH and the WICB Senior Recognition award given by the American Society for Cell Biology in recognition of his work supporting the advancement of women in science. Among StahlLab contributions are the discovery of the lysosomal enzyme clearance pathway now implemented in the treatment of lysosomal storage disease, discovery of the innate immune receptor, the mannose receptor, discovery of the exosome secretion pathway, and the role of Rab5 and Arf6 in endocytosis.

Currently his research focuses on endocytosis, signal transduction, and exosome biogenesis and secretion.

VOLUME EDITORS

Gerald Hart is the Director and DeLamar Professor of Biological Chemistry at Johns Hopkins Medical School. He began his research on glycoconjugates about 40 years ago as a graduate student, and he has been active in the field of Glycobiology ever since. Among his research accomplishments, he determined the minimal sequence requirements for N-linked glycosylation while a postdoc in William Lennarz's lab, and he collaborated with Paul Englund's group at Johns Hopkins to elucidate the biosynthetic pathway for GPI-anchors. In the early 1980s, while probing cells with glycosyltransferases, Hart's laboratory discovered cytoplasmic and nuclear protein glycosylation by O-linked *N*-acetylglucosamine (O-GlcNAc) (e.g., *Journal of Biological Chemistry* 259: 3308; *Journal of Biological Chemistry* 261: 8049). Since that time, the Hart laboratory has published nearly 200 papers on O-GlcNAcylation, identifying and cloning the enzymes controlling cycling, characterizing O-GlcNAcylation and its interplay with phosphorylation on hundreds of proteins, and they have developed many of the tools and methods in use today to study this modification. In

1989, Hart founded the leading journal in the field, *Glycobiology*, serving as Editor-in-Chief until 2001. Hart received the first International Glycoconjugate Organization (IGO) Award in 1997, the Karl Meyer Award from the Society for Glycobiology in 2006, and served as the 2009–2011 president of the IGO. Hart is currently an Associate Editor for *The Journal of Biological Chemistry* and an Associate Editor for *Molecular and Cellular Proteomics*. To date, Hart has published about 263 papers, all in the area of glycosciences. H factor=84.

Bruno Goud studied biochemistry and immunology at the Ecole Normale Supérieure de Cachan and the University of Paris. He received his PhD in 1981 under the mentorship of Jean-Claude Antoine and Stratis Avrameas at Institut Pasteur and did postdoctoral work under the mentorship of Peter Novick at Yale University. In 1995, he established an independent research group in the Department of Cell Biology at the Institut Curie in Paris. The main focus of his studies is the regulation of intracellular transport and membrane trafficking in eukaryotic cells. In particular, his group is working on the functions of Rab GTPases, the mechanisms that sustain the global organization of intracellular compartments and the functions of myosins in membrane traffic. Since 2000, he has also developed original *in vitro* approaches to unravel physical parameters such as membrane tension or membrane curvature that underlie transport processes.

Bruno Goud is a recipient of an ERC (European Research Council) Advanced grant (2013). He is a member of the European Molecular Biology Organization (EMBO). He has been the Head of the Department of Cell Biology of Institut Curie since 2003.

Graça Raposo received her PhD in 1989 in Membrane Biology and Immunology at the University of Paris VII where she specialized in electron microscopy and membrane biology. From 1990 to 1995 she was a postdoctoral fellow at the Immunology Center in Marseille and then in the Department of Cell Biology, Utrecht University, The Netherlands. She is the deputy Director of the Department of Cell Biology at Institut Curie and Director of the Training unit. Her major research interests focus on the biogenesis and functions of exosomes and lysosome related organelles with implications in neurodegenerative disorders, lysosomal diseases, and cancer. Her group have started to unravel the cellular and molecular mechanisms regulating the biogenesis of melanosomes, the lysosome related organelles of epidermal melanocytes, studies that open a new avenue to modulate pigmentation in health and disease. In 2012 she was awarded the CNRS Silver Medal and in 2013 the Descartes Huygens Price from the Royal Dutch Academy of Sciences. She is a member of the European Molecular Biology Organization (EMBO).

Alan Ezekowitz, MBChB, DPhil, FAAP, is Co-Founder, President, and CEO of Abide Therapeutics, a company cofounded by Professors Dale Boger and Ben Cravatt from the Scripps Research Institute. He was previously Senior Vice President and Franchise Head, Bone, Respiratory, Immunology, Endocrine, Dermatology and Urology at Merck Research Laboratories. At Merck, he was responsible for the overall scientific direction of the drug discovery and development process. Prior to Merck, Dr. Ezekowitz was Chief of Pediatric Services at the Massachusetts General Hospital for Children and the Partners Healthcare System and the Charles Wilder Professor of Pediatrics at the Harvard Medical School. He chaired the committee that led to the establishment of the Academy at the Harvard Medical School where he served as a Scholar and Founding member. He served on the Board of Directors of the Partners Healthcare System and Massachusetts General Physicians Organization. In 2008 he was honored with the establishment R. Alan Ezekowitz Professorship in Pediatrics at the Harvard Medical School.

He is a member of the American Society of Clinical Investigation, the Association of American Physicians, the American Pediatric Society, and a Fellow of AAAS. He served on NIH Subcommittees on Biodefense and Vaccine Adjuvants; NAS panels on antibiotic resistance and academic pharmaceutical partnerships; and the ARISE 2 task force of American Academy of Arts & Science that is evaluating the impact of federal and industrial funding of science, engineering, and medicine on American universities.

Dr. Ezekowitz received his MBChB and DPhil from University of Cape Town and Oxford University, respectively. At Children's Hospital in Boston, he was a postdoctoral fellow in the Division of Hematology and Oncology with clinical training in pediatrics. He was on the staff of the Children's Hospital of Boston prior to moving to the Massachusetts General Hospital.

He is a pioneer in the field of innate immunity and has over 150 publications. In particular his group played a major role in defining the structure function of the mannose binding lectin and the macrophage mannose receptor.

Douglas A. Lauffenburger is Ford Professor of Bioengineering, and cofounder and Head of the Department of Biological Engineering at MIT, with affiliate appointment in the Department of Biology; he was a founding codirector of the MIT Computational and Systems Biology Initiative in 2002. His major research interests are in cell engineering, with central focus on cell-cell communication and intracellular signal transduction, emphasizing predictive computational models derived from quantitative experiment. Lauffenburger has coauthored a monograph entitled *Receptors: Models for Binding, Trafficking & Signaling* (Oxford University Press, 1993), has coedited the book entitled *Systems Biomedicine: Concepts and Perspectives* (Elsevier, 2010), and has supervised more than 100 doctoral and post-doctoral students. He is a member of the National Academy of Engineering and the American Academy of Arts and Sciences, and has served as President of the Biomedical Engineering Society, Chair of the AIMBE College of Fellows, and on the NIH NIGMS Advisory Council, and coauthored the NRC report on *A New Biology for the 21st Century*.

SECTION EDITORS

Kenneth E Neet received his PhD in Biochemistry in 1965 (with Dr. Frank W. Putnam) from the University of Florida. He was a postdoctoral fellow at the University of California, Berkeley (with Dr. Daniel E. Koshland, Jr.), and joined the faculty of Case Western Reserve University (CWRU) in 1967 as an Assistant Professor of Biochemistry.

Dr. Neet received a Faculty Research Award of the American Cancer Society from 1968 to 1973 and was on sabbatical leave at the National Institute for Medical Research, Mill Hill, England (with Dr. N. Michael Green) 1973–1974. From 1978 to 1990, he was Professor of Biochemistry at CWRU. During 1980–1981, he took a sabbatical year as a Josiah Macy Faculty Scholar in the Department of Neurobiology, Stanford University (with Dr. Eric M. Shooter).

Dr. Neet moved to Rosalind Franklin University of Medicine and Science/The Chicago Medical School in 1990 and was Professor and Chair of Biochemistry & Molecular Biology until 2005. Dr. Neet became Associate Dean for Research of the Chicago Medical School, RFUMS in 2004.

Dr. Neet has served on the Editorial Boards of the *Journal of Biological Chemistry*, *Protein Science*, and *Molecular & Cellular Proteomics* and as a member of study sections for the National Institutes of Health and the National Science Foundation. He was an Associate Editor of the *Journal of Biological Chemistry* (1996–2013).

Dr. Neet's research interests have been in the general areas of protein–protein interactions, allosteric interactions, protein conformational changes, and cell signaling. In his earlier years he studied theoretical and experimental aspects of slow transitions in enzymes, particularly the cooperativity of the monomeric enzyme glucokinase. Later, he studied ligand–receptor interactions of nerve growth factor, establishing a mutational system to study the interactions with its receptors (TrkA and p75), and ultimately the complex signaling emanating from these receptors within neuronal systems.

Sarah A Woodson is a biophysical chemist interested in how RNA molecules fold into specific three-dimensional structures and how they interact with proteins to turn genes on and off in the cell. She was born in Michigan, USA, and attended Kalamazoo College before receiving her PhD in Biophysical Chemistry from Yale University in 1987. After postdoctoral research in the laboratory of Tom Cech at the University of Colorado Boulder from 1987 to 1990, she joined the faculty of the University of Maryland in 1990 and the faculty of Johns Hopkins University in 1999, where she is currently the T.C. Jenkins Professor of Biophysics. Together with Mark Chance and Michael Brenowitz, she pioneered methods for visualizing how RNA molecules change shape in real time. She served on the board of the RNA Society and was elected an AAAS Fellow in 2011 and a Pew Scholar in the Biomedical Sciences in 1993. She is currently a reviewing editor of *Biopolymers* and *Journal of Molecular Biology* and serves on the editorial boards of *Nucleic Acids Research* and *RNA*.

Judith Bond, Evan Pugh Emeritus Professor of Biochemistry and Molecular Biology at the Pennsylvania State University College of Medicine, was President of the Federation of American Societies for Experimental Biology (2012–13) and an Associate Editor of the *Journal of Biological Chemistry* (1999–2013). She received her BS degree from Bennington College in Vermont, her PhD from Rutgers University, and did postdoctoral research at Vanderbilt University. She rose through the academic ranks at the Medical College of Virginia, Virginia Commonwealth University, became Professor and Head of Biochemistry and Nutrition at Virginia Polytechnic Institute and State University, and served at Penn State University College of Medicine as Professor and Chair of Biochemistry and Molecular Biology from 1992 to 2012. At Penn State, she also served as assistant dean for graduate studies, codirector of the All-University Interdisciplinary Biological Sciences Program and founding director of the Medical Scientist Training Program. She recently directed NIH-funded summer research programs for high school students and teachers and for undergraduate students (particularly underrepresented minority groups). Her work on metalloproteases has been funded continuously by the NIH for over 35 years. She has

trained 5 Master's, 21 PhD students, and 19 postdoctoral trainees. Her professional service included member and chair National Institutes of Health Study Sections, member of the National Institute of Diabetes, Digestive and Kidney Diseases Advisory Council, member of the American Association of Medical Colleges – Howard Hughes Medical Institute Committee on the Scientific Foundations for Future Physicians, and President of the American Society for Biochemistry and Molecular Biology.

Elliot Elson received his AB at Harvard, his PhD at Stanford under the mentorship of R.L. Baldwin and did postdoctoral work at University of California, San Diego, under Bruno Zimm. His first independent faculty position was in the Department of Chemistry, Cornell University, where he stayed for 11 years. He then moved to the Department of Biological Chemistry (now the Department of Biochemistry and Molecular Biophysics) at Washington University in St. Louis, School of Medicine. He has pursued research in several biophysical areas. One of these is the development of Fluorescence Correlation Spectroscopy and Fluorescence Photobleaching Recovery and their application to studies of diffusion in cell membranes and of phase separation in model membrane bilayers as well as of other cellular and noncellular phenomena. He has also worked in the areas of cell mechanics, cell motility, and the mechanical properties of engineered tissues. His laboratory has developed approaches for measuring mechanical properties of cells in monolayer culture and for determining the contributions of cells and extracellular matrix to the mechanics of engineered heart and connective tissue constructs.

Tamotsu Yoshimori received his PhD degree in 1989 at Osaka University. After working at several places including European Molecular Biology Laboratory (Prof. Kai Simons' lab) and National Institute of Basic Biology (Prof. Yoshinori Ohsumi's lab), he is now a distinguished professor of Osaka University (Graduate School of Medicine and of Frontier Biosciences). His research interests are focused on intracellular membrane trafficking, and especially for the last 18 years, on autophagy. He identified LC3 as an autophagosome-binding protein, which has been widely used as the gold standard in autophagy assays. The paper has been cited over 3000 times. He also provided new insights into membrane biogenesis in autophagy and the role of autophagy in pathogen defense and suppression of various diseases. He authored or coauthored over 220 journal articles and book chapters. He is an editor of *Journal Cell Science*, and on the editorial board of *Journal of Cell Biology*, *Molecular Biology of the Cell*, and so on. He is a member of the Faculty of 1000 and a vice president of Japan Society for Cell Biology. He was awarded Osaka University Presidential Award for 2012 and 2013, Prize for Science and Technology by the Minister of Education, Culture, Sports, Science and Technology in 2013, Kakiuchi Saburo Memorial Prize by the Japanese Biochemical Society in 2014, and selected as Highly Cited Researchers 2014 by Thomson Reuters.

Paul A Gleeson is currently Head of the Department of Biochemistry and Molecular Biology at the University of Melbourne, located at Bio21 Institute. His research interests include the molecular mechanisms of intracellular membrane transport and the molecular basis of organ-specific autoimmune diseases. Paul Gleeson obtained his PhD in 1980 from the University of Melbourne and did postdoctoral research in the biosynthesis and function of glycoproteins at the Hospital for Sick Children, Toronto, National Institute for Medical research, Mill Hill London and Department of Biochemistry, La Trobe University, Melbourne. He established an independent laboratory at Monash University in 1986 where he defined the targeting signals of Golgi glycosyltransferases, identified golgins of the *trans*-Golgi network and along with his colleagues developed mouse models of autoimmune gastritis. In 2001 he moved to Department of Biochemistry and Molecular Biology at the University of Melbourne and has been Head of the Department since 2006. He has a number of international research collaborations and has been a visiting scientist at the EMBL, Heidelberg, and the Institut Curie, Paris.

Anna Akhmanova studied biochemistry and molecular biology at the Moscow State University. She received her PhD in 1997 at the University of Nijmegen, the Netherlands. She worked as a postdoc at the Department of Microbiology and Evolutionary Biology at the University of Nijmegen and at the Department of Cell Biology at the Erasmus Medical Center in Rotterdam, the Netherlands. In 2001, she started her own research group at the Erasmus Medical Center. Since 2011, Anna Akhmanova is professor of Cell Biology at Utrecht University, the Netherlands.

Akhmanova studies cytoskeletal organization and trafficking processes, which contribute to cell polarization, differentiation, vertebrate development, and human disease. The main focus of her studies is the microtubule cytoskeleton. Her group has described key interactions between proteins associated with microtubule ends and determined their role in the regulation of microtubule organization and dynamics. She has also characterized mechanisms of bidirectional microtubule-based motility of membrane organelles such as cell nuclei and exocytotic vesicles. Her research relies on combining high-resolution live cell imaging and quantitative analysis of cytoskeletal remodeling, measurement of protein dy-

namics using advanced microscopic assays, *in vitro* reconstitution of dynamic cytoskeleton-based processes and different methods of identification of protein–protein interactions.

Anna Akhmanova is a recipient of the ALW Vernieuwingsimpuls VIDI (2001) and VICI awards (2007) (Netherlands Organization for Scientific Research), and an ERC Synergy grant (2013). She is the Chair of the board of the Netherlands Microscopy Society and a member of the European Molecular Biology Organization (EMBO).

Yosef (Yossi) Yarden is a Professor in the Department of Biological Regulation at Weizmann Institute of Science (Rehovot, Israel). Dr. Yarden obtained his PhD from Weizmann Institute (under the mentoring of Dr. Joseph Schlessinger) and later trained at both Genentech Inc., with Dr. Axel Ullrich, and at the Whitehead Institute (MIT), with Dr. Robert A. Weinberg. His group studies the roles played by growth factors and their receptors in cancer progression. They also explore strategies able to intercept growth factor signals in tumors.

Jason D Weber is an Associate Professor in the Departments of Internal Medicine and Cell Biology and Physiology at Washington University and is the Coleader of the Breast Cancer Research Program in the Siteman Comprehensive Cancer Center. Dr. Weber obtained his PhD from Saint Louis University and received postdoctoral training under the mentoring of Dr. Charles J. Sherr at St. Jude Children's Research Hospital in Memphis, TN. His group studies the molecular interplay between oncogenes and tumor suppressors, particularly focused on their role in regulating cellular growth processes.

Michael Dustin received his PhD in 1990 in Cell and Developmental Biology from Harvard University, where he worked in the laboratory of Timothy A. Springer, PhD. During his graduate work he was involved in the identification and cloning of ICAM-1 and ICAM-2, key ligands for the integrin LFA-1. He further demonstrated that LFA-1 dependent adhesion was stimulated by T cell receptor signaling. He did his postdoctoral training with Stuart Kornfeld at Washington University School of Medicine in St. Louis, focusing on mechanisms of lysosome biogenesis. He started his independent lab also at Washington University School of Medicine, and used supported lipid bilayers to define the first protein to modulate organization of the immunological synapse- CD2 associated protein- and the dynamics of immunological synapse formation. He moved to NYU School of Medicine in 2001 where he applied *in vivo* microscopy to tolerance induction and immune responses in effector sites including the liver, brain, and spleen. Continued work with the immunological synapse model resulted in discovery of signaling microclusters, the molecular basis of immunological synapse stability, and the direct budding of extracellular microvesicle enriched in T cell receptors in the immunological synapse. Professor Dustin recently took a position at the

University of Oxford with support of a Wellcome Trust Principal Research Fellowship. The focus of his new post is the translation of the immunological synapse. He received a Presidential Early Career Award in Science and Engineering and the DART-NYU Biotechnology Achievement Award.

David Sassoon directs a research team at Paris Sorbonne. He received his PhD from Columbia University (NYC, USA) in 1986 in the biological sciences and was a professor at Boston University Medical School and Mt. Sinai Medical School before relocating to Paris in 2006. His long-standing interests are in developmental and stem cell biology in a number of tissues including skeletal muscle, skin, CNS, and heart. Dr. Sassoon recently concluded the coordination of a EC-funded 15 partner international consortium (Endostem) designed to identify novel therapeutics for mobilizing endogenous stem/progenitor cells (<http://www.endostem.eu/>) and is a recent recipient as coordinator of a multipartner Transatlantic Network of Excellence grant from the Fondation Leducq focused on cardiac stem cell biology (<http://www.fondationleducq.org/nivel2.aspx?idsec=1360>).

A major focus of his research is on adult progenitor/stem cell biology and how these cells respond to stress. His team has identified a parentally imprinted gene, PW1/Peg3, which is involved in both p53 and inflammatory responses. PW1 is expressed in adult stem cells in all tissues identified to date. Loss of PW1 function in stem cells results in a loss of stem cell competence including a reduced capacity to undergo self-renewal and respond to hypoxic stress. We are currently evaluating a role for PW1 in postnatal and adult heart with a particular focus on its role in vessel precursors using both myocardial infarction and stress-induced myocardial hypertrophy.

Jason M Haugh is a Professor of Chemical and Biomolecular Engineering at North Carolina State University in Raleigh, NC, USA, where he has been on the faculty since 2000. His laboratory has been among those to pioneer the synthesis of quantitative experiments and modeling to study signal transduction in mammalian cells. Since the lab's inception, their approach has combined biochemical measurements, live-cell fluorescence microscopy, and computational modeling to elucidate signaling mechanisms by analyzing their kinetics and spatial organization in cells. The systems studied by the Haugh Laboratory include: regulation of the phosphoinositide 3-kinase, Ras/extracellular signal-regulated kinase, and phospholipase C pathways mediated by receptor tyrosine kinases, and cross talk between these pathways; dynamic organization of multimolecular complexes at cell membranes; signaling mediated by cytokine and chemokine receptors in immune cells; and integration of adhesion, signaling, and cytoskeletal dynamics that direct cell migration.

After graduating with an MA in Mathematics from the University of Cambridge, Helen Mary Byrne received her Master of Science and DPhil from the University of Oxford. She worked as a postdoctoral researcher at the Universities of Oxford and Bath, before taking up a lectureship at the UMIST in Manchester. She moved to the University of Nottingham in 1998 and was awarded a prestigious Advanced Research Fellowship from the United Kingdom's Engineering and Physical Sciences Research Council (2000–2006). She was promoted to Reader in 2002 and Professor in 2003. While in Nottingham, she established and then led the Centre for Mathematical Medicine and Biology until she returned to Oxford in 2011 where she is now based in the Mathematical Institute at the University of Oxford. She has over 20 years' experience of developing, analyzing, and simulating continuum and multiscale models of biomedical systems, and a particular interest in studying the growth and response to treatment of solid tumors.

Rune Linding completed his PhD at the European Molecular Biology Laboratory (EMBL) in Heidelberg, Germany, followed by postdoctoral training at EMBL. He then jointly trained with professors Tony Pawson and Mike Yaffe at the Lunenfeld at Mount Sinai Hospital in Toronto, Canada, and the Massachusetts Institute of Technology (MIT) in Cambridge, US, respectively. Dr. Linding then established his own laboratory of Cellular and Molecular Logic at the Institute of Cancer Research (ICR) in London, UK, before returning to Denmark to take a position as professor of cellular signal integration at the Technical University of Denmark. In 2014, Dr. Linding moved his laboratory to the Biotech Research and Innovation Centre (BRIC) at University of Copenhagen where he is currently professor of cellular signaling. His research group focuses on big data network biology, exploring biological systems by developing and deploying algorithms aimed to predict cell behavior, in particular looking at cellular signal processing and decision making. A strategic focus is to continue to develop computational tools (such as KinomeExplorer, NetworKIN, and NetPhorest) and to deploy these on genome-scale quantitative data obtained by, for example, mass spectrometry, genomic, and phenotypic screens to understand the principles of how spatio and temporal assembly of mammalian signaling networks transmit and process information at a systems level in order to alter cell behavior. His overarching aim is to advance network

medicine by identifying and targeting signaling networks associated with complex diseases. To this end Dr. Linding is currently leading high-level, strategic, multidisciplinary studies of signaling network dynamics driving cancer metastasis in collaboration with other labs at Harvard, Yale, The Jackson Laboratory, Memorial Sloan Kettering Cancer Center, MIT, and BRIC.

CONTENTS OF VOLUME 1

Preface	xxv
Cell Biology: An Overview <i>RA Bradshaw and PD Stahl</i>	xxvii

Molecular Cell Biology

Molecular Cell Biology: An Overview <i>KE Neet, SA Woodson, JS Bond, and GW Hart</i>	1
--	---

Molecular Principles, Components, Technology, and Concepts

Basic Principles

Chemical and Physical Principles <i>H Oubrahim and P Boon Chock</i>	5
Biocatalysis <i>PA Frey and GH Reed</i>	14

Nucleic Acids

DNA, RNA Chemical Properties (Including Sequencing and Next-Generation Sequencing) <i>M Datto and RL Lundblad</i>	24
The Chemical Synthesis of DNA and RNA Oligonucleotides for Drug Development and Synthetic Biology Applications <i>SL Beaucage and HV Jain</i>	36

Proteins

Expression Systems <i>DI Fisher, LM Mayr, and RG Roth</i>	54
Isolation/Purification of Proteins <i>GA Grant</i>	66
Protein Sequence Determination: Methodology and Evolutionary Implications <i>RA Bradshaw</i>	75
Posttranslational Modifications: Key Players in Health and Disease <i>I Lindberg and JR Peinado</i>	84
Protein Domains: Structure, Function, and Methods <i>DA Korasick and JM Jez</i>	91
NMR in Structural and Cell Biology <i>G Marius Clore</i>	98
Folding, Misfolding, Disordered Proteins, and Related Diseases <i>LM Longo and M Blaber</i>	108
Diseases of Protein Folding: Huntington's Disease and Amyotrophic Lateral Sclerosis <i>BJ Bailus and LM Ellerby</i>	115
Site-Directed Mutagenesis <i>KW Walker</i>	122
Chemical Biology <i>RL Lundblad</i>	128
Drug Design <i>RL Lundblad</i>	135
Antibodies and Improved Engineered Formats (as Reagents) <i>PJ Hudson</i>	141

Lipids

Lipidomics <i>BM Kenwood and AH Merrill Jr.</i>	147
Synthesis and Structure of Glycerolipids <i>W Dowhan</i>	160
Cholesterol and Other Steroids <i>S Sitaula and TP Burris</i>	173

Glycolipids	<i>AH Merrill Jr. and MN Vu</i>	180
Lipid Signaling	<i>B Tu-Sekine and DM Raben</i>	194

Membranes

Composition, Physical Properties, and Curvature	<i>B Antonny</i>	201
Lipid Rafts/Membrane Rafts	<i>E London</i>	208
Membrane Potential: Concepts	<i>AJ Moorhouse</i>	218
The Outer Mitochondrial Membrane, a Smooth 'Coat' with Many Holes and Many Roles: Preparation, Protein Components, Interactions with Other Membranes, Involvement in Health, Disease, and as a Drug Target	<i>PL Pedersen and YH Ko</i>	237
Neuronal Action Potentials and Ion Channel Allostery	<i>SE Kotermanski and M Cascio</i>	244
Cystic Fibrosis	<i>NA Bradbury</i>	252

Carbohydrates

Glycogen and Starch	<i>PJ Roach and SC Zeeman</i>	263
Proteoglycans	<i>PW Park, K Hayashida, RS Aquino, and A Jinno</i>	271
Hyaluronan	<i>VC Hascall, PH Weigel, and BP Toole</i>	279

Metabolism

Metabolic Regulation	<i>MS Patel and RA Harris</i>	288
A Structure Perspective on Organelle Bioenergetics	<i>WA Cramer and SK Singh</i>	298

Nucleic Acid Synthesis/Breakdown

RNA Synthesis/Function

Transfer RNA	<i>J Doherty and M Guo</i>	309
Messenger RNA (mRNA): The Link between DNA and Protein	<i>DJ Goss and AV Domashevskiy</i>	341
The Interplay between Eukaryotic mRNA Degradation and Translation	<i>W Hu</i>	346
miRNAs/Small Noncoding RNAs	<i>R Fukunaga</i>	354
Small RNAs/Cancer	<i>BM Ryan</i>	364
Riboswitches and Ribozymes	<i>MWL Lau and AR Ferré-D'Amaré</i>	375
Ribosomal RNAs and Protein Synthesis	<i>S Joseph</i>	384
Comparison of Bacterial and Eukaryotic Replisome Components	<i>NY Yao and ME O'Donnell</i>	396

DNA Synthesis/Repair

Telomeres and Telomerase	<i>JJ-L Chen and JD Podlevsky</i>	418
Telomere Biology	<i>DC Teasley and SA Stewart</i>	426
Eukaryotic Nucleotide Excision Repair	<i>B Van Houten and M Kong</i>	435
The Base Excision Repair Pathway	<i>JL Parsons and MJ Edmonds</i>	442

Nonhomologous DNA End Joining	<i>S Sharma and SC Raghavan</i>	451
DNA Repair by Homologous Recombination	<i>SS Jenkins, S Mukherjee, and W-D Heyer</i>	456
Transcription		
Prokaryotic Transcription	<i>DM Hinton</i>	468
Eukaryotic Transcriptional Regulation	<i>BA Lewis</i>	481
Distant Activation of Transcription by Enhancers	<i>O Kulaeva and VM Studitsky</i>	488
The Spliceosome and Pre-mRNA Splicing	<i>TJ Carrocci and AA Hoskins</i>	495
Pre-mRNA Splicing: Function and Dysfunction	<i>AM Case, IA Sawyer, M Dundr, and ML Hastings</i>	503
Nucleic Acid Technology		
Transgenesis and Gene Replacement	<i>MJ Wolfgang</i>	512
Viral Nucleic Acids	<i>IP O'Carroll and A Rein</i>	517
Protein Synthesis/Degradation		
Translation		
Components, Initiation, Elongation, Termination, and Regulation	<i>AA Komar and WC Merrick</i>	525
Biogenesis of Secretory Proteins	<i>Z Chang</i>	535
The Protein Biosynthetic Machinery of Mitochondria	<i>LL Spremulli</i>	545
Regulated Proteolysis of Signaling Molecules: The Proprotein Convertases	<i>B Ramos-Molina, I Lindberg, and JR Peinado</i>	555
Protein Degradation – General		
Mass Spectrometry-based Methodologies for Studying Proteolytic Networks and the Degradome	<i>N Solis and CM Overall</i>	568
Protein Degradation – Intracellular		
Ubiquitin, Ubiquitin-Like Proteins, and Proteasome-Mediated Degradation	<i>RJ Dohmen, JM Huibregtse, and M Scheffner</i>	582
Endoplasmic Reticulum-Associated Degradation and Protein Quality Control	<i>LF Zacchi, JJ Caramelo, AA McCracken, and JL Brodsky</i>	596
Role of Lysosomes in Intracellular Degradation	<i>M Hafner Česen, V Stoka, and B Turk</i>	612
Protein Degradation – Protease Classes		
Matrix Metalloproteinases	<i>G Murphy</i>	621
ADAMTS Proteases: Mediators of Physiological and Pathogenic Extracellular Proteolysis	<i>SS Apte</i>	630
ADAMs Regulate Cell–Cell Interactions by Controlling the Function of the EGF-Receptor, TNF α and Notch	<i>CP Blobel</i>	639
Extracellular: Plasma Membrane Proteases – Serine Proteases	<i>TM Antalis and MS Buzza</i>	650
Aspartic Proteases of Alzheimer's Disease: β - and γ -Secretases	<i>MS Wolfe</i>	661

The Calpain Proteolytic System	<i>Y Luo, DF Sellitti, and K Suzuki</i>	670
Cathepsin E: An Aspartic Protease with Diverse Functions and Biomedical Implications	<i>K Yamamoto, K Okamoto, and T Tsukuba</i>	681
Metalloproteases Meprin α and Meprin β in Health and Disease	<i>C Tredup and C Becker-Pauly</i>	691
Kallikrein	<i>RA Bradshaw and RL Lundblad</i>	699
Naturally-Occurring Polypeptide Inhibitors: Cystatins/Stefins, Inhibitors of Apoptosis (IAPs), Serpins, and Tissue Inhibitors of Metalloproteinases (TIMPs)	<i>K Brew and M Lizotte-Waniewski</i>	706
Proteolytic Pathways		
Overview of Blood Coagulation and the Pathophysiology of Blood Coagulation Disorders	<i>JC Cardenas, CM Rein-Smith, and FC Church</i>	714
Molecular Mechanisms Underlying the Actions of the Complement System	<i>RN Pike and LC Wijeyewickrema</i>	723
Digestive Proteases: Roles in the Human Alimentary Tract	<i>SG Bradley</i>	732
Protein Degradation – Pathological Aspects		
Inhibitors of HIV Protease	<i>A Wlodawer and M Jaskolski</i>	738
Blood Pressure, Proteases and Inhibitors	<i>NE Clarke and AJ Turner</i>	746
Cancer – Proteases in the Progression and Metastasis	<i>K Ji and BF Sloane</i>	753
Lysosomal Diseases	<i>TM Cox</i>	763
Alpha-1-Antitrypsin Deficiency: A Misfolded Secretory Glycoprotein Damages the Liver by Proteotoxicity and Its Reduced Secretion Predisposes to Emphysematous Lung Disease Because of Protease-Inhibitor Imbalance	<i>S Chakraborty, DH Perlmutter, and Amitava Mukherjee</i>	789

PREFACE

Cell biology is the study of cells, the integral unit that is the basis of all living tissues. In its earliest phases, this area of investigation was largely defined by microscopic-based observations of structure and organization that were, by their nature, largely descriptive. This also served to delineate cell biology from its nearest neighbor, biochemistry, which, dating from its post WWII renaissance, was driven in large part by reductionist approaches, where tissues, cells, and organelles were broken down in order to isolate and then characterize individual components. The melding force that bridged these two areas was molecular biology that allowed the cell biologist to transform pictures into functions and allowed the biochemist to reassemble their components into ensembles and subcellular entities. Not surprisingly the boundary between these two key biological sciences has become blurred beyond recognition. Today a considerable part of what passes as cell biology is by any other name biochemistry (or molecular biology – the distinction between these two areas being equally indistinct) and vice versa. Indeed, one of the first challenges we faced in organizing this Encyclopedia was how much molecular detail to include. It was our conclusion that for the sake of completeness, and to appropriately introduce the volumes Organizational Cell Biology and Functional Cell Biology, we needed a description of the molecular components of the cell, particularly with respect to the synthesis and degradation of proteins and nucleic acids, along with outlines of important chemical principles and key methodology. We were guided to some degree in these decisions by input from undergraduate and graduate teachers and the contents of their introductory courses that they shared with us and by discussions with our volume and section editors. The result was the first volume which we recognize is very 'biochemical,' but certainly lacking the more detailed coverage of the *Encyclopedia of Biological Chemistry* (Lennarz and Lane, 2004) or the many excellent biochemical texts that dot the educational landscape. Readers who find 'gaps' or incomplete treatments in this section will likely be able to find the additional detail they seek from these sources.

The second major decision that we had to confront was whether we would attempt to cover the full range of living organisms or whether we would place some limits on the scope of the material we included. In the final result, it was decided to place the emphasis on higher eukaryotes with only very prescribed treatments of lower eukaryotes and prokaryotes. Volumes 2 and 3 thus deal with material that has perhaps been more traditionally thought of as cell biology. Again we were guided in our decisions about what to include by teaching considerations, brainstorming sessions with our editors, and a perceived need to separate cellular organization from cellular function. However, as even a quick perusal will reveal, this is not a sharp delineation either. Volume 2 begins with a methodological treatment of imaging, which is basically divided between light and electron microscopic applications, and is followed by sections on organelles, interorganellar communication, and the cytoskeleton (including motors). The

last part of volume 2 is devoted to intracellular infection and covers a variety of external agents and pathogens that impact cell function as well as human pathology. Volume 3, in contrast, largely deals with major cell functions: signaling, cell-cycle control, and apoptosis. The last two parts are devoted to cells of the immune system and their responses and stem cells – two highly specialized niches characterized by unique cellular involvement.

The last part of the Encyclopedia deals with systems biology. This is really the newest area of cell biology and considers cellular involvement as part of a phenotypic response. As such, it strives to integrate all of the levels of the first three volumes in a consistent manner to produce a seamless description of cellular function. This is clearly a newly evolving area and the most rapidly changing part of cell biology; indeed it is where we expect to see the greatest change in the next few years.

Assembling a treatment of a topic as large as cell biology had multiple challenges. Coverage was a significant problem: on the one hand it was almost impossible to avoid some redundancy in places while, on the other, there were inevitable gaps. Some of these arose from late cancellations; others from oversights on our part. We can only promise to fill these in future editions. We also note that as can be expected for a large multiauthor compilation the individual articles do differ in detail and treatment. We felt it was more important to allow our experts substantial latitude in deciding how to present their topics than to apply rigid guidelines. We did try to limit the number of references (to make it easier for people not familiar with a topic to make the transition to more extensive articles) but there is admittedly some considerable variation in the bibliographic material as well.

When we were well into the project, we were approached by Graham Nisbet (Elsevier) about including the Encyclopedia in a larger collection entitled the Reference Module in Biomedical Sciences. The Reference Module plan was grouped in single integrated work information from several other compendia and it was our view that this would greatly leverage the value of our efforts (and those of our contributors). While we were the 'new kid on the block' in that we were still compiling the Encyclopedia and the other collections to be included were already extant, we felt that it was too good an opportunity to pass up. The Reference Module has since been launched and although it does not yet contain the complete content from the Encyclopedia, this will be achieved in the not too distant future. We consider that this will be a particularly valuable resource for researchers that are just entering (or changing into) this field.

No work of this size could be completed without the help and advice of many people. In this regard we would like to thank a number of people who were instrumental in bringing this project to fruition. First and foremost we would like to recognize our volume editors: Jerry Hart, Graça Raposo, Bruno Goud, Alan Ezekowitz, and Doug Lauffenburger; and our section editors: Ken Neet, Sarah Woodson, Judy Bond,

Elliot Elson, Tamotsu Yoshimori, Paul Gleeson, Anna Akhmanova, Yosef Yarden, Jason Weber, Michael Dustin, David Sassoon, Jason Haugh, Helen Byrne, and Rune Linding; and thank them for their invaluable input, enthusiasm, and hard work. They are truly a global group and have been a great team to work with. We also wish to thank the staff at Elsevier including Janice Audet, Peter Labella, Nicky Carter, Karen Maloney, Erin Hill-Parks, Rashmi Phadnis, Blerina Osmanaj, and Ginny Mills for their many efforts, perseverance (particularly with our idiosyncrasies), and skillful management of every aspect of this project.

In the course of planning this work, we gathered information from a number of sources. At the outset the publishers polled some 167 faculty from both undergraduate and graduate schools to ascertain their perceived interest in such a project, which also garnered considerable input about potential topics. The response was highly favorable. We also talked with many colleagues about experiences at their institutions and would like to particularly thank Catherine Bevier (Colby College), Robert Simoni (Stanford University), Larry Marsh (UC Irvine), and John Cooper (Washington University) for providing syllabi of germane courses taught in their institutions. Special thanks also go to Ruedi Abersold (ETH, Zurich) and Sergio Grinstein (University of Toronto) for their expertise that they readily shared with us, which was invaluable in planning certain sections.

Finally we would like to recognize all of our authors. We have been extraordinarily fortunate in attracting individuals from all around the globe to take time from their busy schedules to prepare this splendid set of contributions. Without these efforts there would be no Encyclopedia. Under ordinary circumstances it would be appropriate to dedicate the work to them and all the colleagues whose works they wrote about. However, during the preparation of this work, we sadly lost one of the most important contributors to cell biology, Tony Pawson. Tony was a true pioneer in elucidating basic mechanisms of how cells transmit information intracellularly, a fundamental knowledge that permeates all of cell biology. In an effort that was initiated by one of the section editors, Rune Linding, it was decided to dedicate the entire work to his memory as recognition of his contributions and a lasting tribute to a man who left us too soon.

We hope that the Encyclopedia will be of value to students and researchers alike and will become a useful tool in the training of future generations of scientists.

Ralph A Bradshaw and Philip D Stahl

All living organisms can be divided into three principal categories: archaeobacteria, eubacteria, and eukaryotes; although they differ in structure and organization, they are all composed of cells as the fundamental life unit. At the molecular level, there is also a great deal of similarity in the basic materials that make up these entities because they use the same kinds of molecules to store and reproduce information, to run the cellular metabolism and machinery and to provide the structural framework. Thus nucleic acids, proteins, lipid membranes, and carbohydrates – alone and in various combinations – are universally present, albeit in distinguishable forms, along with innumerable metabolites and ions. There are components that are apparently essential for life and are found in one form or another in all species and there are many unique moieties and associated activities that are highly specialized and are found in relatively few organisms. Indeed, the similarities have underpinned the development of our understanding of cellular function at a rudimentary level and the differences, basically engendered by evolution, have illustrated and delineated the complexity that speciation has introduced. Perhaps the largest of these differences is that which separates single cell organisms from multicellular organisms. The latter are exclusively eukaryotes while the former are composed of both eukaryotes and prokaryotes. The cellular organization and architecture that distinguishes these two major life forms is striking; although cell biology correctly embraces both, traditionally prokaryotic organisms have been the province of the microbiologists and the majority of cell biology research has been devoted to the eukaryotic world. In practical terms this translates for the most part into the study of human cells and those of easily maintained laboratory animals and selected paradigms, for example, fruit flies, worms, and zebra fish.

Human and animal cell biology is not a tightly proscribed science with well-defined borders. Basically it serves at the interface between biochemistry, molecular biology, and genetics, on the one hand, and anatomy and physiology, on the other. The continuum of these disciplines forms the core of the biomedical sciences, which also include the related but separate fields of pharmacology, microbiology, immunology, and pathology that provide the connections to disease and health. Cell biology has strong connections to all of these. There are also specialized areas, for example, neuroscience, that are of such importance that they warrant their own category and the cell biology associated with them is also highly specialized. Thus, cell biology is as complex as the enormous variety of cells that exist and achieving an accurate description of all of them in terms of their components and functions has long been a major part of the research in this field.

Imaging and Organelle Organization

Among the developments that propelled cell biology into the modern era are the introduction of the ultracentrifuge and

the rapid advances in microscopy both electron and light microscopy – the former allowing investigators to fractionate and characterize the components of the cell and the latter to literally see them – either *in situ* or in isolated form. This progress is illustrated by a series of Nobel Prizes starting in the early 1970s that chronicle the grand confluence of classical biochemistry and general physiology that created modern cell biology (Claude *et al.*, 1974) or the discovery and characterization of intracellular organelles – lysosomes and endoplasmic reticulum (ER) among others (Mitchell, 1978), for the chemiosmotic hypothesis (Brown and Goldstein, 1985), for endocytosis (Ciechanover *et al.*, 2004), for ubiquitination and protein degradation, and just recently (Rothman *et al.*, 2013), for vesicle trafficking, and (Betzig *et al.*, 2014) for advances in light microscopy. The early cell biologists insisted on quantitative application of these new techniques and laid the groundwork for modern cell biology. As with biochemistry, reductionism has been the keystone for the amazing success over these past several decades. Each organelle has its own research history – the nucleus, mitochondria, peroxisomes, the proteasome, the ER, and cytoskeleton. The Golgi apparatus/secretory pathway and the endosome–lysosome network have all been examined in detail both in isolation and in their relationships with each other. A new member, the exosome (aka extracellular vesicle) has emerged more recently and stimulated the imagination of aspiring young investigators (Harding *et al.*, 2013). The rise of genomics, the development of spectacular imaging modalities, and evolving biochemical techniques (proteomics) have led to the discovery of molecular motors, the identification of macromolecular complexes such as the exocyst, ESCRT, GARP, SNAREs among others that choreograph complex intracellular pathways, including cell motility and cytokinesis, have brought cell biology into this new era where the whole is now seen as larger than the individual components. This creates the segue from Parts 1 and 2 of the *Encyclopedia (Molecular Cell Biology and Organizational Cell Biology)* to Part 3 (*Functional Cell Biology*) where signaling modalities will be seen as an integrative force for regulation and control.

Signaling

While all organisms can sense their environment and respond to cues from it, multicellular organisms must in addition coordinate their responses, which require intercellular communication at a sophisticated level (Bradshaw and Dennis, 2009). The higher the development, the more complex these communication systems become. Thus the cell biologist must focus not only on how molecular function is translated into cell organization and how these functions are coordinated from organelle to organelle but also on the external interactions and signals that control the larger functional responses of organs and ultimately organisms.

Intercellular communication is afforded by stimuli that can be transmitted across the cell membrane, either directly or via membrane bound molecules that in turn pass signals to the intracellular compartment. The origins of these stimuli may be quite diverse. Among other things, they can include cell–cell contacts, soluble factors/messengers, or foreign agents. Lipophilic molecules can cross the membrane by diffusion or by facilitated transport to recognize and bind to intracellular entities but most substances bind to membrane bound proteins and induce their signal by ‘activating’ them instead. These so-called receptors are capable of producing a variety of responses that invariably involve the generation of posttranslational modifications of preexisting proteins. Protein phosphorylation, which in eukaryotes mostly occurs on tyrosine, serine, and threonine residues, is highly prevalent and appears to be directly or indirectly involved in almost all transmembrane signaling (Gnad *et al.*, 2011). However, it is by no means the only vehicle for transmitting information as acetylation, methylation, monoglycosylation, and ubiquitination, to name a few, are both important and widespread. There are over three hundred different covalent modifications (Khoury *et al.*, 2011) that are introduced into proteins (and many more that have not yet been chemically defined) of both a transient and stable nature and most are likely to be involved to some extent in signal transduction processes. In addition, limited proteolysis can also be an important part of a pathway and this activity is a major player in cellular responses (Turk *et al.*, 2012).

The induction of an intracellular signal is basically perpetrated by the formation of new interactions between the modified proteins and other entities, which can range from small molecules to macromolecular protein complexes. One of the most important advances in understanding how cells process information induced from external stimuli was the appreciation that the newly formed sites produced by the protein modifications were recognized by other proteins with modules specifically designed for this purpose (Pawson, 1995). Thus, for example, phosphotyrosine residues could be recognized by other proteins containing a domain, termed SH2 for its relatedness to a similar domain found in the Src protein kinase, which could then be further modified allowing for additional interactions to occur. By these ‘docking’ events, signaling complexes could be assembled, often in multiple steps, that ultimately lead to the activation of key effectors. The end point of many of the pathways is the activation of transcription factors that lead to the modulation of gene expression of that cell by ultimately changing its protein expression profile (Bradshaw and Dennis, 2009). However, many molecules are usually modified and activated ‘along the way’ and these ‘new’ activities also add to the overall response to the original stimuli. Short term responses indeed require that the protein effectors necessary for it are already present; long term responses per force require new protein synthesis.

Signal transduction is thus dependent on two phenomena: posttranslational modifications, particularly of the readily reversible type, and protein–protein interactions. The extent to which these two activities take place, even in resting, unstimulated cells was greatly underestimated before the advent of proteomics and the introduction of mass spectrometric methodology into cell biological research (Bradshaw and

Burlingame, 2005). These high-throughput unbiased analyses of very complex mixtures, basically derived directly from cell lysates, revealed that essentially every protein had multiple interacting partners and that posttranslational modifications affected a very significant proportion of the proteins present. These were profound differences from what had been the prevailing wisdom and amounted to a paradigm shift in thinking about cellular organization and structure. As noted above, these same tools have gone on to cast new light on organelle organization in terms of resident proteins and have helped to disclose the structure of important cellular machines, such as the proteasome (Voges *et al.*, 1999), the nuclear pore (Routa *et al.*, 2000), and transcription complexes (Kornberg, 2007). They have also begun to elucidate the complexity of epigenetic regulation of gene transcription at the histone level (Cosgrove, 2012), which will also be essential in completing our understanding of signaling processes.

Concluding Remarks

Two of the most fundamental aspects of cells are their ability to reproduce themselves and, in higher organisms, to undergo changes that lead to new cell types and functions. These developmental processes leading to differentiation are what allow a single fertilized egg to form a complex adult organism and require the synthesis of all aspects of cell biology to understand. Knowing how cells go from one state to another in a timed and regulated fashion forms the core of developmental biology, which can be viewed as a sub discipline of cell biology. Also of major importance is the maintenance of viability and the associated turnover processes. The control of cell death is not only an essential part of development it is also key to managing situations that have gone awry and underlies many serious disease conditions.

It is clear that science is still a long way from understanding how even simple cells work. There is a long list of functions and structures that remain to be elucidated and integrating the various experimental approaches and the data they produce still lags far behind. This is the ‘Era of Big Data’ and vast amounts of new information that impact on our understanding of cells and their processes are collected every day. Genomic information is a good example – despite the rapidity that this sort of information can now be obtained, it still remains to be effectively mined in terms of what it can tell us about basic principles of how cells work. There has been an understandable pressure to apply this information to managing disease (Collins and Varmus, 2015), particularly those that are life threatening, but there certainly is information that is yet to be formulated that would apply to fundamental problems as well. The same can be said for transcriptomics, proteomics, and metabolomics. In addition to these powerful new technologies, singular advances in analyzing single cells promises to augment these molecular approaches significantly (Di Palma and Bodenmiller, 2015).

One aspect of cell biology that is looking to address the challenges of integrating these relatively newly minted studies is systems biology (Part 4). It is far too early to assess the value of these efforts in coordinating this flood of information but it certainly looks promising. It will be an elusive goal for some

time to come but also a stimulus for new generations of cell biologists that will be forthcoming.

Basic Molecular Components and Technology

The history of cell biology is rooted in the related sciences of biochemistry and molecular biology. Biochemistry grew from physiology and chemistry early in the twentieth century and gave fruit to molecular biology in mid-century. The term 'cell biology' first appeared in PubMed in 1917, occurred sparsely for many years, crossed the 10 paper per year mark in 1948, did not reach 1000 papers per year until the mid-1980s, and currently appears in more than 25 000 papers per year. The driving force of this explosion of information is the inherent interest in biological systems, i.e., ourselves, as well as the intrinsic importance to medicine, i.e., ourselves in a pathological state.

As these sciences moved into the twentieth century, the dividing lines among these disciplines became blurred so that an *Encyclopedia of Cell Biology* must begin with a presentation of the essentials of biochemistry and molecular biology that are needed to understand cell biology. Currently, these disciplines are nearly indistinguishable with a considerable overlapping continuum. Good investigators follow significant research questions regardless of what discipline is involved in the solutions. Biology follows a continuum from atom to molecule to system to organism. Advances in these related scientific areas could not have been made without parallel development of experimental techniques capable of asking and answering the appropriate questions. This first subsection **Basic Molecular Components and Technology** leads to the remainder of the first major section of the Encyclopedia, **Molecular Aspects/Molecular Principles, Components, Technology, and Concepts Important for Understanding Cell Biology** and deals with evolving techniques that have helped elucidate the nature of the molecules, complexes, organelles, cells, and interactions involved in living organisms. The emphasis is not on the techniques themselves, but rather on what the technology reveals about the basic components of biological cells and systems.

The early 'central dogma' of 'DNA makes RNA makes protein' has become outdated since the discovery of reverse transcription in certain RNA viruses and the discovery of catalytic RNA. The concept of one gene for one protein had to be expanded and modified due both to splicing and post-translational modifications. The terminology of noncoding DNA as 'junk' DNA has been made passé by microRNA and other types of noncoding RNA. Thus, the field of biochemistry/molecular biology/cell biology, like with all science, advances. Indeed, as the evolution of the understanding of cell biology has progressed, we have found broader concepts to replace

simpler ones resulting in an ever-increasing appreciation of the complexity of structure, function, regulation, and growth of living organisms. Many of these principles and molecules fundamental to cell biology have also been treated from a somewhat different perspective and format in the related Elsevier publication '*Encyclopedia of Biological Chemistry*,' second edition, and should be consulted for additional information.

Since life is based on chemistry, the *Encyclopedia of Cell Biology* starts with certain chemical principles of equilibria, bonding, and catalysis before moving into structural considerations. The biological structures discussed are the four usual major classes of biomolecules: nucleic acids, proteins, lipids, and carbohydrates. More complex molecules/systems encompass more than one of these groups, for example, glycoproteins glycolipids, lipoproteins, and membranes. Several articles are devoted to metabolites and metabolism ('classical' biochemistry and essential for functioning of cells). Certain diseases that are linked to molecular function or dysfunction, for example, cystic fibrosis (see [Cystic Fibrosis](#)) and Huntington's disease (see [Diseases of Protein Folding: Huntington's Disease and Amyotrophic Lateral Sclerosis](#)), are specifically presented.

Topics making up the first section, in order, are basic chemical principles (including equilibria) (see [Chemical and Physical Principles](#)), bonding (see [Chemical Biology](#)), and catalysis (see [Biocatalysis](#)); nucleic acids (including chemical properties and sequencing) (see [DNA, RNA Chemical Properties \(Including Sequencing and Next-Generation Sequencing\)](#)), chemical synthesis (see [The Chemical Synthesis of DNA and RNA Oligonucleotides for Drug Development and Synthetic Biology Applications](#)), cloning and expression systems (see [Expression Systems](#)) and site-directed mutagenesis (see [Site-Directed Mutagenesis](#)); Proteins (including structure and domains) (see [Protein Domains: Structure, Function, and Methods](#)), folding and misfolding (see [Folding, Misfolding, Disordered Proteins, and Related Diseases; Diseases of Protein Folding: Huntington's Disease and Amyotrophic Lateral Sclerosis](#)), posttranslational modifications (see [Posttranslational Modifications: Key Players in Health and Disease](#)), drug design (see [Drug Design](#)), antibodies (see [Antibodies and Improved Engineered Formats \(as Reagents\)](#)), sequencing (see [Protein Sequence Determination: Methodology and Evolutionary Implications](#)), purification (see [Isolation/Purification of Proteins](#)) and spectroscopy (see [NMR in Structural and Cell Biology](#)); Lipids (including cholesterol) (see [Cholesterol and Other Steroids](#)), complex lipids (see [Synthesis and Structure of Glycerolipids; Glycolipids](#)), signaling (see [Lipid Signaling](#)) and

lipidomics (see [Lipidomics](#)); Membranes (including properties and biogenesis) (see [Composition, Physical Properties, and Curvature](#)), rafts (see [Lipid Rafts/Membrane Rafts](#)), electrochemical potential (see [Membrane Potential: Concepts](#)), nerves (see [Neuronal Action Potentials and Ion Channel Allostery](#)) and mitochondria (see [The Outer Mitochondrial Membrane, a Smooth 'Coat' with Many Holes and Many Roles: Preparation, Protein Components, Interactions with Other Membranes, Involvement in Health, Disease, and as a Drug Target](#)); Complex carbohydrates (including glycogen) (see [Glycogen and Starch](#)), proteoglycans (see [Proteoglycans](#)) and hyaluronan (see [Hyaluronan](#)); and Metabolites (including regulation) (see [Metabolic Regulation](#)), bioenergetics and organelles (see [A Structure Perspective on Organelle Bioenergetics](#)).

Nucleic Acid Synthesis/Breakdown

Deoxyribose nucleic acid (DNA) was first discovered in 1869 by the Swiss scientist, Friedrich Miescher. Nucleic acids are biopolymers comprised of nucleotide monomers that are composed of three moieties, a five-carbon sugar, a phosphate group, and a nitrogenous base. DNA contains deoxyribose as the sugar component and RNA contains the sugar ribose. Polynucleotides are formed by covalent linkages between the phosphate of one nucleotide and the sugar of another, resulting in phosphodiester linkages. Nucleic acids are the major information molecules of all known forms of life by encoding, transmitting, and expressing genetic information. Elucidation of the structure of DNA by Watson and Crick in 1953 immediately suggested the semiconservative mechanism by which DNA is accurately reproduced and later demonstrated by Meselson and Stahl. The ability of DNA sequences to be copied into RNA or into copies of DNA with high fidelity in a template-dependent fashion is one of the most fundamentally important processes in living organisms. The transfer of genetic information from DNA to RNA to protein is considered the fundamental process of all living systems. However, as occurs in certain viruses, it is possible to transfer sequence-encoded information from RNA to DNA by reverse transcription. Topics in this section of the *Encyclopedia of Cell Biology* cover all major roles of nucleic acids in information transfer, including the mechanisms by which genetic information is regulated. This section additionally covers how RNA molecules transmit, edit, splice, and regulate the expression of genetic information – processes that greatly increase the number of combinations in which protein-coding sequences can be used.

Topics in this section, in order, are: [Comparison of Bacterial and Eukaryotic Replisome Components](#), which describes the structures and mechanisms of the protein machinery that replicates DNA in bacteria and eukaryotes; [Transfer RNA](#), which not only describes how tRNAs serve as adaptor molecules to translate mRNA sequences into protein sequence but also describes tRNA's roles in many other cellular processes; [Messenger RNA \(mRNA\): The Link between DNA and Protein](#) compares mRNA's structure/functions in bacteria and eukaryotes and how mutations in untranslated

regions of mRNAs contribute to human disease; [Telomeres and Telomerase](#) describes the end-capping structures, called telomeres, on eukaryotic chromosomes that are critical for chromosome stability, and discusses the importance of telomerase enzymes in maintenance of the telomere; [Telomere Biology](#) describes how telomeres maintain genome stability and prevent cellular senescence, and how cancer cells bypass the normal limits on telomere elongation to gain immortality; [Small RNAs/Cancer](#) reviews the discovery, biogenesis, and roles of microRNAs in cancer etiology; [Eukaryotic Nucleotide Excision Repair](#) describes highly conserved DNA repair mechanisms that remove and repair a wide variety of chemical lesions in DNA structure, which in some cases contribute to the onset of cancer; [The Base Excision Repair Pathway](#) reviews a pathway that is critical to genomic stability by correcting small DNA base lesions, first by excising the damaged locus, and then by replacing damaged nucleotides with the correct ones; [Nonhomologous DNA End Joining](#) describes and compares how cells repair double-strand breaks in DNA by either nonhomologous DNA end joining or by homologous recombination (HR) mechanisms; [DNA Repair by Homologous Recombination](#) reviews mechanisms and proteins involved in repairing complex DNA damage by HR and how specific HR proteins protect stalled replication forks; [Prokaryotic Transcription](#) reviews the current understanding of transcription in bacteria from the recognition of DNA to the termination of RNA synthesis; [Eukaryotic Transcriptional Regulation](#) describes current models of transcriptional regulation in eukaryotes; [Distant Activation of Transcription by Enhancers](#) reviews how distantly-acting DNA enhancers activate transcription by chromatin looping; [miRNAs/Small Noncoding RNAs](#) describes how precursor mRNAs in eukaryotes are spliced to remove intervening sequences by a complex ribonucleoprotein complex called the spliceosome; [Pre-mRNA Splicing: Function and Dysfunction](#) further expands on the process of splicing pre-mRNA and describes human diseases resulting from dysregulation of the splicing machinery; [Ribosomal RNAs and Protein Synthesis](#) discusses the structure of ribosomes and how the ribosomal RNA functions in the synthesis of proteins; [miRNAs/Small Noncoding RNAs](#) reviews our current knowledge about the biological synthesis and processing of microRNAs, which are typically 22 nucleotides long and function in translational repression and other regulatory processes; [The Interplay between Eukaryotic mRNA Degradation and Translation](#) summarizes current views on how eukaryotic mRNA degradation interconnects with mRNA translation to regulate gene expression; [Riboswitches and Ribozymes](#) describes the biological roles and potential as tools of riboswitches and ribozymes, which are regions of mRNA that regulate gene expression by binding small molecules, or are RNA that catalyze chemical reactions, respectively; [Transgenesis and Gene Replacement](#) presents an overview of the most widely used methods for experimentally manipulating the genomes of mammals to understand gene functions; and see [Viral Nucleic Acids](#) provides an overview of viral genomes, which can be either RNA or DNA, and how they are replicated in host cells. This collection of articles on nucleic acids not only provide the reader a comprehensive understanding of the state of the science in nucleic acid research, but also provides

a solid foundation for more focused investigations into the topic.

Protein Synthesis and Degradation

This section focuses on molecular mechanisms underlying the regulation of protein concentration and active forms of proteins both inside and outside cells and highlights diseases/pathologies that can result in dysregulation of proteins. Just as the knowledge/understanding of RNA and DNA and other fundamental components of cells and tissues have evolved, so have those of the proteins that make up cells, the extracellular environment, and fluids of living organisms. The complexity of the interactions of proteins has become apparent and the importance of networks of proteins (death pathways, blood coagulation, complement), interacting proteases (the 'protease web'), extracellular matrix, intracellular scaffolds, and membrane, organelle, and factor interactions with intracellular and extracellular proteins are now clearly realized.

Many of the structures involved in the synthesis of proteins have been solved (including the ribosome, translation factors) and there has been considerable progress clarifying the mechanisms that control initiation, elongation, and termination in eukaryotic cells (see [Components, Initiation, Elongation, Termination, and Regulation](#)). Similarly the components of the mitochondrial protein biosynthetic machinery and mechanisms of transcription and translation have been elucidated (see [The Protein Biosynthetic Machinery of Mitochondria](#)). Many proteins are synthesized as inactive or latent proteins (proproteins) and have to be activated by enzymes such as proprotein convertases and kallikreins (see [Regulated Proteolysis of Signaling Molecules: The Proprotein Convertases; Kallikrein](#)). Biosynthesis of secretory proteins that takes place in the endoplasmic reticulum (ER) involves multiple factors (signalases, chaperones, isomerases) to form a mature correctly folded protein (see [Biogenesis of Secretory Proteins](#)). Factors are in place for quality control in the ER to recognize and shuttle incorrectly folded proteins into the ER-associated degradation pathway (see [Endoplasmic Reticulum-Associated Degradation and Protein Quality Control](#)).

It was once believed one protease could degrade many proteins in a relatively unregulated manner (somewhat like trypsin in the intestinal tract). It is now known that there are multiple proteases in all cells and fluids that are highly regulated. There are ~600 genes for proteases in the human genome and if there were no regulation there would be widespread necrosis, cell death, and destruction. It is clear that proteolytic systems are highly regulated by localization, activation/inhibition, synthesis of latent proenzymes, interactions with multiple components such as cofactors, carbohydrates, lipids, membranes, organelles, and the pH of the environment. The complement of all proteases and their substrates is known as 'the degradome' and high-throughput methods have recently been developed to study the network of protease and substrate interactions (see [Mass Spectrometry-based Methodologies for Studying Proteolytic Networks and the Degradome](#)).

Proteolytic systems exist both intracellularly and extracellularly as well as at cell membranes. The mammalian intestinal system serves as a good example of coordinated digestion of food proteins that involves many different types of extracellular proteases (see [Digestive Proteases: Roles in the Human Alimentary Tract](#)). Blood coagulation represents another extracellular system that is critical to host defense and hemostasis and involves cells (e.g., platelets), a host of plasma proteins (most of which are proteases) and protease inhibitors, which are highly controlled to form and degrade blood clots appropriately (see [Overview of Blood Coagulation and the Pathophysiology of Blood Coagulation Disorders](#)). The complement system involves highly regulated proteolytic enzymes critical to our immune systems that remove targeted pathogens (see [Molecular Mechanisms Underlying the Actions of the Complement System](#)). The proteasome is key to intracellular proteolytic systems and works in coordination with ubiquitin-tagged proteins for protein quality control and several signaling systems (see [Ubiquitin, Ubiquitin-Like Proteins, and Proteasome-Mediated Degradation](#)). In addition, the intracellular lysosomal system containing multiple hydrolases (e.g., proteases, glycosidases) that interact with cellular and extracellular components to degrade and maintain protein/amino acid homeostasis (see [Role of Lysosomes in Intracellular Degradation](#)). Dysregulation of all of these systems is associated with disease, and there are specific articles on lysosomal storage diseases (see [Lysosomal Diseases](#)) and the proteases involved in the progression of cancer (see [Cancer – Proteases in the Progression and Metastasis](#)).

Individual proteases are discussed in many articles and some that are highlighted are matrix metalloproteinases (see [Matrix Metalloproteinases](#)), calpain (see [The Calpain Proteolytic System](#)), ADAMS and ADAMTS (see [ADAMTS Proteases: Mediators of Physiological and Pathogenic Extracellular Proteolysis; ADAMs Regulate Cell–Cell Interactions by Controlling the Function of the EGF-Receptor, TNF \$\alpha\$ and Notch](#)), membrane-anchored serine proteases (see [Extracellular: Plasma Membrane Proteases – Serine Proteases](#)), meprins (see [Metalloproteases Meprin \$\alpha\$ and Meprin \$\beta\$ in Health and Disease](#)), kallikreins (see [Kallikrein](#)), and aspartic proteases (see [Aspartic Proteases of Alzheimer's Disease: \$\beta\$ - and \$\gamma\$ -Secretases; Cathepsin E: An Aspartic Protease with Diverse Functions and Biomedical Implications](#)). Protease inhibitors are also critical to the regulation of protein degradation and disease. Endogenous polypeptide protease inhibitors exist for many of the proteolytic systems (e.g., apoptosis, blood coagulation; [Naturally-Occurring Polypeptide Inhibitors: Cystatins/Stefins, Inhibitors of Apoptosis \(IAPs\), Serpins, and Tissue Inhibitors of Metalloproteinases \(TIMPs\)](#)). Alpha-1-antitrypsin deficiency is an example of how important endogenous protein inhibitors are for preventing disease, as this deficiency leads to liver damage and emphysema (see [Alpha-1-Antitrypsin Deficiency: A Misfolded Secretory Glycoprotein Damages the Liver by Proteotoxicity and Its Reduced Secretion Predisposes to Emphysematous Lung Disease Because of Protease-Inhibitor Imbalance](#)). Examples of synthetic protease inhibitors used to control disease process are blood pressure inhibitors (ACE inhibitors; [Blood Pressure, Proteases and Inhibitors](#)) and HIV-protease

inhibitors that have been designed to manage AIDS (*see* [Inhibitors of HIV Protease](#)).

In summary, the purpose of part I of the Encyclopedia is to describe the chemical principles and the molecular components/organization of the cell and its environment in

sufficient detail to allow a clearer understanding of how these components are then assembled, function, and are regulated at a higher level – the themes of the next three parts of the Encyclopedia.

Introduction

Cells of all living organisms contain four classes of macromolecules or polymers consisting mainly of carbon, oxygen, nitrogen, hydrogen, and a small quantity of sulfur and phosphate atoms. Proteins are polymers of amino acids, which serve as enzymes, regulators, structure elements, and receptors; DNA and RNA are polymers of nucleotides, which store and transmit genetic information, and polysaccharides are polymers of simple sugars, which serve as energy-rich fuel stores. To investigate the molecular processes that make life possible, it is essential that investigators are well versed in fundamental chemical and physical principles, since they govern both the thermodynamics and dynamics of biochemical processes.

Living cells must perform work to stay alive, grow, replicate, and evolve, while maintaining themselves in a dynamic steady state, far from equilibrium with their environment. To understand how cells accomplish these processes, within the topic limitation of this article, we focus our discussion on the physical and chemical principles that govern interactions between cellular molecules. They include the energetic aspect that determines whether a molecular process can occur spontaneously, and the kinetic and regulatory aspects of biological processes, as well as effects of the crowded cellular environment.

The Laws of Thermodynamics and Living Cells

Living cells have developed highly efficient mechanisms to utilize the energy obtained from chemical fuels and light to carry out numerous energy-requiring processes in order to maintain themselves in dynamic steady states. When a cell fails to obtain energy, it will die and decay toward equilibrium with its surroundings. To understand how the energy is extracted, stored and channeled into useful work in living cells, we address cellular energy conversions in context of the law of thermodynamics and the quantitative relationships among free energy, enthalpy and entropy.

The laws of thermodynamics are general principles that provide the quantitative description of heat and energy changes and chemical equilibria. These laws apply to all chemical and physical processes, including biochemical reactions ([van Holde *et al.*, 1998](#); [Edsall and Gutfreund, 1983](#); [Alberty, 2003](#)). Their importance resides in the fact that they determine the conditions in which a biochemical reaction can proceed.

In thermodynamics, the field of observation is divided into two conceptual regions: the system and the surroundings. The 'system' refers to everything within a defined region of space, including all the constituent reactants, products, solvent of the reaction, and the immediate atmosphere; while the system and its surroundings together constitute the universe. When the system does not exchange either matter or energy with its surroundings, it is considered isolated. If the system exchanges only energy and not matter with its surroundings, it is defined as a closed system. An open system is one that exchanges both matter and energy with its surroundings. The first law of thermodynamics describes the principle of the conservation of energy. In any physical or chemical change, the total energy, E , of a system and its surroundings is constant, although the form of the energy may vary. In other words, the first law states that E can be changed only by the flow of energy as heat or by work. Consequently, energy can neither be created nor destroyed, it can only be changed from one form to another as shown in the mathematical expression below,

$$\Delta E = E_B - E_A = Q - W \quad [1]$$

where E_A and E_B is the energy of a system at the beginning and the end of the transformation, respectively, Q is the heat absorbed, and W is the work done by the system. Note the change in energy of a system depends only on the initial and final states, independent of the transformation pathway.

When a given chemical reaction occurs under constant pressure, the amount of heat released or absorbed reflects the nature and number of chemical bonds altered during the course of the reaction. This heat of reaction is referred to as enthalpy, H , expressed as joules/mol or calories/mol

(1 cal = 4.184 J). Because the total enthalpy of a system cannot be measured directly, only the change of enthalpy, ΔH , is evaluated. If heat is being absorbed by the reaction, its ΔH is positive and the reaction is endothermic. On the other hand, if heat is generated by the reaction, the reaction is exothermic and its ΔH is negative. However, the first law of thermodynamics is insufficient to predict whether a reaction can occur spontaneously since some endothermic reactions do occur spontaneously. Thus, a function other than ΔH is necessary to account for this observation. One such function is the entropy, S , expressed in unit of J/mol K. Note that entropy is a quantitative expression for the randomness or disorder in a system. When the products of a reaction are less complex and more disordered than the reactants, the reaction proceeds with a gain in entropy. It is worth mentioning that entropy is a central concept in biochemistry since life requires continual maintenance of order while increased randomness is the natural tendency. The second law of thermodynamics states that a process can occur spontaneously, if and only if, the sum of the entropies of the system and its surroundings is > 0 . This indicates that the entropy of a system can decrease during a spontaneous reaction, if the entropy of the surroundings increases such that their sum is positive. However, the entropy changes of chemical reactions are not readily determined and the second law indicates that to determine whether the reaction can occur spontaneously requires one to know the value of the entropy changes for both the surroundings and the system of interest. At constant temperature and pressure, a condition fulfilled by most biological systems, this constraint imposed by the second law can be obviated by using a different thermodynamic state function termed free energy (G) or Gibbs' free energy, derived from the combining of the first and second law of thermodynamics by Gibbs (1876–1878, 1878).

The basic equation is:

$$\Delta G = \Delta H - T\Delta S \quad [2]$$

where ΔG is the change in Gibbs free energy of a reaction under constant pressure, P , and temperature, T , and ΔS and ΔH is the change in entropy and in enthalpy of the reaction, respectively.

Gibbs Free Energy Always Decreases for a Spontaneous Process at Constant Temperature and Pressure

All reactions are generally affected by two forces: The tendency to achieve the most stable chemical bond, indicated by ΔH , and the tendency to achieve the highest degree of randomness, expressed by ΔS . The net effect of these two factors is summed up by the change of Gibbs free energy described by eqn [2]. Thus, ΔG provides a valuable criterion for determining whether a reaction can occur spontaneously. By convention, ΔS is positive when entropy increases and ΔH is negative when heat is released by the system to its surroundings. When either of these conditions is energetically favorable the reaction tends to yield a negative ΔG , a condition for a spontaneous reaction. To determine the actual free energy change, ΔG , for the reaction [3], one needs to take into account the nature of the reactants and products as well as their concentrations as shown

in the eqn [4].

where a , b , c , and d represent the stoichiometry of the indicated components.

$$\Delta G = \Delta G^0 + RT \ln \left(\frac{[C]^c [D]^d}{[A]^a [B]^b} \right) \quad [4]$$

where ΔG^0 is the standard free energy change, a constant that is characteristic of each reaction, R is the gas constant, T is the absolute temperature, and $[A]$, $[B]$, $[C]$ and $[D]$ are molar concentrations of reactants and products. (More precisely, the activity, defined as a thermodynamic function that correlates changes in chemical potential with changes in concentration, through relations formally equivalent to those for ideal systems. For practical reasons, molar concentration is used in biochemical literature.) ΔG^0 is the change in free energy under standard conditions (298 K and 1 atm) when reactants and products are initially present at 1 M, or for gas at 1 atm. Equation [4] indicates that ΔG of a reaction depends on the nature of the reactants, expressed by ΔG^0 , and their concentrations, expressed by the second term of the equation.

With this definition, the standard state for reactions involving hydrogen ions is $[H^+] = 1$ M or pH 0. However, most biochemical reactions occur in relatively well buffered aqueous media at a pH around 7, such that both the pH and the concentration of water (55.5 M) are essentially constant. To simplify ΔG^0 calculation, biochemists adopted a convention that in the biochemical standard state, $[H^+]$ is 10^{-7} M (pH7), $[H_2O]$ is 55.5 M, and when the reactions involve Mg^{2+} (when ATP is a reactant), $[Mg^{2+}]$ is 1 mM, a standard state different from that used in chemistry and physics. With this convention, when H_2O , H^+ , or Mg^{2+} are reactants or products, their concentrations are not included in the K_{eq} expression, but are incorporated, with a value of 1 for each of their activities, into the constants K'_{eq} and $\Delta G'^0$. These constants are referred to as standard transformed constants written with a prime, to distinguish them from the standard constants used by chemists and physicists. Thus, the standard transformed free energy change at pH 7 is denoted as $\Delta G'^0$, which can be calculated using the equilibrium constant, K'_{eq} , and the equation $\Delta G'^0 = -RT \ln K'_{eq}$ where $K'_{eq} = \frac{[C]_{eq}^c [D]_{eq}^d}{[A]_{eq}^a [B]_{eq}^b}$. Therefore, the criterion for the spontaneity of a biochemical reaction depends on the value of ΔG , expressed as

$$\Delta G = \Delta G'^0 + RT \ln ([products]/[reactants]) \quad [5]$$

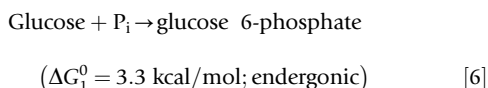

Gibbs Free Energy Changes are Additive

The free energy change of a reaction is independent of its reaction pathway. However, when a reaction consists of two or more successive reactions, and each of the two successive reactions shares a common intermediate, the Gibbs free energy change of the net reaction is equal to the sum of the ΔG of the individual reactions. In other words, the Gibbs free energy changes are additive. This property allows one to determine the free energy of the formation of complex molecules needed to sustain living cells, from ΔG of the individual reaction steps that lead to the formation of the final complex molecules.

Consequently, a thermodynamically unfavorable reaction, with a positive ΔG , can be driven by a thermodynamically favorable reaction to yield a negative ΔG for the sum of free energy changes of the two reactions. Utilizing this energy-coupling strategy, biological systems are able to synthesize and maintain the information-rich polymers required to sustain living cells, and to formulate their metabolic pathways by coupling enzyme-catalyzed reactions such that the overall ΔG of the pathway is negative. In biological systems, this principle is frequently utilized to couple the energy of ATP hydrolysis, a highly exergonic reaction, to otherwise unfavorable reactions, such as those involved in the biosynthetic pathways.

Coupling of ATP Hydrolysis to Drive Thermodynamically Unfavorable Reactions

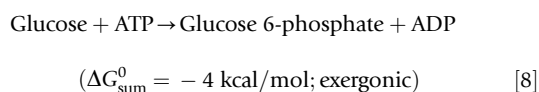

ATP, maintained at a relatively high and constant level in the cell, has been considered as the molecular currency of intracellular energy transfer. It has been extensively utilized to drive thermodynamically unfavorable biochemical pathways. To illustrate how this principle works, we consider the coupling of ATP hydrolysis to the synthesis of glucose 6-phosphate, an endergonic first reaction step in glucose oxidation pathway:

where P_i is inorganic phosphate. $K_{\text{eq}1} = [\text{Glucose 6-phosphate}] / ([\text{Glucose}][\text{P}_i]) = 10^{(-\Delta G_1^0/1.36)} = 3.98 \times 10^{-3} \text{ M}^{-1}$ at 25°C (Note $2.3 \times RT = 1.36 \text{ kcal mol}^{-1}$). This indicates that there is no net conversion if the molar ratio is equal to or larger than $3.98 \times 10^{-3} \text{ M}^{-1}$. When this reaction is coupled to:

where $K_{\text{eq}2} = ([\text{ADP}][\text{P}_i]) / [\text{ATP}] = 2.18 \times 10^5 \text{ M}$. The sum of these two reactions becomes

The equilibrium constant of this coupled reaction becomes

$$K_{\text{eq}} = K_{\text{eq}1} \times K_{\text{eq}2} \\ = ([\text{Glucose 6-phosphate}][\text{ADP}]) / ([\text{Glucose}][\text{ATP}]) \\ = 10^{(-\Delta G_{\text{sum}}^0/1.36)} = 8.7 \times 10^2.$$

At equilibrium, the ratio of $[\text{Glucose 6-phosphate}] / [\text{Glucose}][\text{P}_i] = K_{\text{eq}} \times [\text{ATP}]_{\text{eq}} / ([\text{ADP}]_{\text{eq}}[\text{P}_i]_{\text{eq}})$.

The ATP generating system in cells maintains the $[\text{ATP}]_{\text{eq}} / ([\text{ADP}]_{\text{eq}}[\text{P}_i]_{\text{eq}})$ at a high level, typically on the order of 500; thus

$$[\text{Glucose 6-phosphate}] / ([\text{Glucose}][\text{P}_i]) = 8.7 \times 10^2 \\ \times 500 = 4.35 \times 10^5 \text{ M}^{-1}$$

Together, this indicates that by coupling the conversion of glucose to glucose 6-phosphate to ATP hydrolysis in the cell,

under standard conditions would shift the equilibrium ratio of $[\text{Glucose 6-phosphate}]$ to $[\text{Glucose}] \times [\text{P}_i]$ by a factor of 10^8 .

This example demonstrates the thermodynamic essence of ATP's action as an energy-coupling agent. Since all living cells maintain a concentration of ATP much higher than its equilibrium concentration, coupling of a cellular reaction with the hydrolysis of an ATP molecule can change the equilibrium ratio of products to reactants by a huge factor, for example, by a factor of 10^8 . Thus, ATP functions as a major carrier of chemical energy in cells to convert thermodynamically unfavorable reaction sequences into favorable ones.

Reaction Rate and Rate Constant

Note that ΔG of a reaction depends only on the nature of the reaction and the concentration of both reactants and products, but ΔG is independent of the mechanistic pathway. Furthermore, ΔG does not provide information on the rate of a chemical reaction. In fact some thermodynamically favorable reactions fail to take place at measurable rates due to the high activation energy required for the reactions. To overcome this problem, biological systems utilize enzymes to catalyze slow reactions by lowering the activation energy via an alternative reaction pathway to facilitate the formation of the transition state. Like all catalysts, enzymes cannot alter the equilibrium constants of a reaction. They only increase the rate by which a reaction proceeds in the direction governed by thermodynamics. In other words, thermodynamics cannot provide information about intervening states of the system.

While thermodynamics predicts whether a reaction can occur, and how much energy can be derived from them, the concentration of most molecules in living cells is maintained in dynamic steady states, and not by equilibrium constants. Therefore, rates of biochemical reactions, mostly catalyzed by enzymes, play an important role in shaping the metabolic pathways in living cells. The fact that about a quarter of the protein-encoding genes in the human genome encode enzymes and their regulatory proteins points to the importance of understanding the kinetics of biochemical reactions in cellular regulation and metabolism (For further reading on kinetics, see references [Moore and Pearson, 1981](#); [Purich, 2010](#); [Connors, 1990](#)).

The rate, $d[\text{P}]/dt$, for the formation of a reaction product, P , is determined by the concentration of the reactant(s) and its rate constant, k . In general, a rate equation has the form

$$d[\text{P}]/dt = k[\text{S}_1]^a[\text{S}_2]^b \dots \quad [9]$$

The value of k is independent of the concentration of S_1 , S_2 , ..., but dependent on the nature of reaction investigated, and the environmental conditions of the reaction, such as temperature and chemical properties of the reaction medium. The power variables a and b represent the order of reaction with respect to S_1 and S_2 , respectively, and their sum ($a + b + \dots$) represents the overall order of the reaction. When eqn [9] is in a form of simple rate equations, it represents the rate expression of elementary (single-step) reactions. Some complex (multiple step) reactions may also possess simple rate equations. Nevertheless, complicated rate equations are required for

kinetic analysis of complex reactions such as those involving parallel or consecutive reactions.

When a reaction is unimolecular, eqn [9] is reduced to $d[P]/dt = k[S_1]$. In this case, the rate of the reaction depends only on k and the concentration of S_1 . This reaction is defined as a first-order reaction, and k is a first order-rate constant that has a unit of reciprocal time, for example, s^{-1} . A first-order reaction proceeds via an exponential function and its half-life, $t_{1/2} = \ln 2/k$ or $0.693/k$, can be used to calculate its rate constant. Note that the $t_{1/2}$ of a first-order reaction is constant, independent of the initial time point used for analysis. In the case of a bimolecular reaction, the reaction rate depends on the concentration of two different reactants, or two molecules of the same reactant, such that $d[P]/dt = k[S_1]^2$ or $k[S_1][S_2]$, where k is the second-order rate constant, with an unit of $M^{-1}s^{-1}$. The time course of the second-order reaction is qualitatively similar to that of the first-order reaction, except the consumption of the reactant(s) proceeds faster initially and slower toward the end of the reaction due to the nature of second-order dependency. A third-order reaction, whose rate depends on the product of three concentrations, is relatively rare. In the case of a zero-order reaction, its rate is independent of the concentration of the reactant, and the unit of its rate constant is $M s^{-1}$. A zero-order reaction proceeds with a linear time course. This type of reaction is not commonly observed except in heterogeneous systems and in catalyzed reactions when the catalyst is present at a significantly lower concentration than that of the reactant, such that the catalyst is saturated with the reactant. Under this condition, the concentration of the reactant will not change significantly during the course of the initial rate measurement, and the reaction rate depends only on the concentration of the catalyst used.

Reaction Rate-Limiting Step

When the conversion of reactant S to product P proceeds via formation of a number of intermediates, for example, I_1 and I_2 , and if the formation of I_1 , I_2 , or P is very much slower than the rest of the reaction steps, then the rate of P formation will be limited by the rate of the slowest step, a reaction that possesses the highest activation energy, $\Delta G^\ddagger$. This slowest step is called a rate-limiting or rate-determining step since it is the 'bottleneck' of the overall reaction. Strictly speaking, this flow analogy is valid only for consecutive and irreversible reactions, and it can be misleading if the reverse reaction is significant. In fact even for irreversible reactions, the rate-determining step concept is meaningful only if one of the reactions is much slower than the others. Note when the overall reaction includes more than two elementary steps, the situation may not be easy to analyze, since the product of the n th step is the reactant of the $(n+1)$ st step. For these two states to be represented by the same free energy they must have the same composition. This means that the stoichiometric composition must be constant throughout the entire successive reactions (Boyd, 1978).

Rate Constant and Activation Energy

To co-relate the magnitude of a rate constant to Gibbs free energy of activation, $\Delta G^\ddagger$, a transition-state theory was derived.

This theory assumes that the transition state is in equilibrium with reactants, such that the population of the transition state is governed by Gibbs free energy of activation, $\Delta G^\ddagger$. Thus, the magnitude of a rate constant can be expressed as a function of Gibbs free energy of activation and temperature:

$$k = (k_B T/h)(e^{-\Delta G^\ddagger/RT}) \quad [10]$$

where k_B is the Boltzmann constant, and h is the Planck's constant. The important point to emphasize here is that the relationship between the rate constant and the activation energy, $\Delta G^\ddagger$, is inverse and exponential. In other words, this is the basis for the statement that lower activation energy yields a faster reaction rate.

Enzyme Kinetics

Equation [10] shows that the function of catalysts is to lower the activation energy, $\Delta G^\ddagger$, of a reaction and thereby speed up the reaction rate. Most of the catalysts in biological systems are enzymes, and the majority of enzymes are proteins. The majority of enzymes are known to catalyze only one particular type of reaction under very limited chemical and physical conditions, and they are capable of enhancing a reaction rate up to factors of 10^6 or more. Enzyme-catalyzed reactions are characterized by the formation of an enzyme-substrate, ES, complex. The catalytic specificity and capacity of an enzyme are derived mainly from multiple weak interactions between the enzyme and its substrates, mediated by hydrogen bond formation, hydrophobic, and ionic interactions. Furthermore, the enzyme active site tends to be structured such that some of these interactions occurred specifically to stabilize the transition state. The need for multiple interactions could be one of the reasons that an enzyme is a relatively large size molecule. The enzyme-substrate binding energy could be utilized to offset the energy required for activation, as well as to induce protein conformational change at the active site to properly position catalytic functional groups to facilitate the cleavage and formation of chemical bonds by a variety of mechanisms, including general acid-base catalysis, covalent catalysis, and metal ion catalysis. These processes could lead to transient covalent interactions with a substrate or group transfer to or from the enzyme, to provide a new, lower-energy reaction pathway. Once the catalytic action is completed, including the release of the tightly bound product(s), the enzyme reverts to its unbound state.

Multiple techniques have been employed to elucidate the catalytic mechanism of purified enzymes. They include three-dimensional structural analysis of enzymes, coupled with chemical modification and site-directed mutagenesis to examine the role of individual amino acid residues in enzyme structure and action. However, kinetic study of enzyme action remains the most important method for elucidating the mechanistic action of enzymes. Kinetic properties of many enzymes can be described by the Michaelis-Menten model. In this model, an enzyme, E , first forms an ES complex, where S is the substrate, prior to product, P , formation.

The initial rate of product generation can be described by the Michaelis–Menten equation:

$$v = V_{\max}([S]/([S] + K_M)) \quad [12]$$

where $V_{\max}$ is the reaction rate when the enzyme is fully saturated with the substrate and K_M is the Michaelis constant, $K_M = (k_{-1} + k_2)/k_1$. When k_2 is rate-limiting such that $k_2 \ll k_{-1}$, K_M is reduced to k_{-1}/k_1 , the dissociation constant of ES. It should be pointed out that the validity of the steady-state method does not depend on the assumption that $d[ES]/dt = 0$. This assumption is not valid at the beginning of the reaction when [ES] is being built up, and toward the end of the reaction when [S] is too low to maintain a constant [ES]. This problem was resolved by Wong in 1975 (Wong, 1975) as follow:

Based on the reaction scheme shown in eqn [11],

$$d[ES]/dt = k_1[S]([E]_0 - [ES]) - (k_{-1} + k_2)[ES] \quad [13]$$

The initial rate of product formation is,

$$v = k_2[ES] = k_2(k_1[S][E]_0 - d[ES]/dt)/(k_1[S] + k_{-1} + k_2) \quad [14]$$

When $d[ES]/dt$ is small relative to $k_1[S][E]_0$ where $[E]_0$ is the total concentration of the enzyme used, then

$$v = k_2[ES] = k_1k_2[S][E]_0/(k_1[S] + k_{-1} + k_2) \quad [15]$$

During the early phase of the reaction, if $[S] \gg [E]_0$, the rate of change in [ES] due to diminishing [S] will be relatively slow. Thus, the validity of steady state is closely tied to the high substrate to enzyme ratio. The maximal rate, $V_{\max} = k_2[E]_0$, and k_2 , also known as k_{cat} , or turnover number, is the number of substrate molecules being converted into product per unit time at a single catalytic site when the enzyme is fully saturated with substrate. The ratio k_{cat}/K_M provides a good indication of the catalytic efficiency of an enzyme. Note that the Michaelis–Menten equation is also applicable to bisubstrate reactions, which proceed via a ternary complex or double-displacement pathways. A short-hand method of expressing two or more substrates or products has been proposed by Cleland to differentiate order, random, Theorell–Chance, and Ping–Pong mechanisms (Cleland, 1963). It should be pointed out that while the kinetic constants can be accurately determined from *in vitro* study using a high substrate to enzyme ratio, this unique condition required for validating the Michaelis–Menten equation may not be met under cellular conditions. Therefore, one needs to be cautious in drawing conclusions from steady-state kinetic study under such circumstances because it can lead to intolerably high errors if analyzed with the unmodified Michaelis–Menten expression (Cha, 1970).

Allosteric Enzymes

All enzymes that exhibit hyperbolic kinetics with respect to increasing substrate concentration follow Michaelis–Menten kinetics, and their K_M represents the [S] required to achieve a rate equal to half $V_{\max}$. However, the Michaelis–Menten model fails to account for the kinetic properties of many enzymes. An important group of enzymes that do not obey Michaelis–Menten kinetics are the allosteric enzymes. An Allosteric

enzyme/protein is one in which binding of one substrate or ligand to one site affects the binding affinity of another site in the same molecule. When binding of one ligand impairs the subsequent binding of other ligands, its kinetics exhibits a negative cooperativity. In contrast, the activity of most allosteric enzymes displays a sigmoidal kinetics due to substrate binding at one site that promotes the subsequent binding affinity at a distinctly different site. This group of enzymes is generally, but need not, consists of multiple subunits or multiple active sites. They play a crucial role in many fundamental biological processes, including, but not limited to, cell signaling and metabolism regulation since they are susceptible to be regulated by signaling molecules. With the sigmoidal saturation response, the value of [S] at half-maximal rate cannot be designated as K_M because the enzymatic activity does not follow a hyperbolic function. Thus, the symbol $S_{0.5}$ or $K_{0.5}$ is often used to represent the substrate concentration required to achieve half-maximal velocity of the allosteric enzyme. It should be pointed out that this class of enzyme has important regulatory properties. On one hand, sigmoidal kinetics provides a mean for allosteric enzymes to greatly alter their catalytic output in response to a relatively small change in substrate/effector concentration. On the other hand, an enzyme with a strong negative cooperativity can provide a means for a rapid surge or decrease in enzymatic activity through changes in the concentration of an effector that desensitizes the negative cooperativity (Huang *et al.*, 1982). Interestingly, to date, among the known allosteric proteins, oxygen binding to hemoglobin, an oxygen carrying protein consists of four oxygen binding sites, is the most thoroughly studied. Consequently, hemoglobin is sometimes being referred to as an ‘honorary allosteric enzyme.’

From a kinetic standpoint a multisubunit enzyme is not required to achieve a cooperative type of kinetics, since it can be generated by a monomeric enzyme that can exist in several conformations at steady state or utilize alternative pathways in a multisubstrate reaction. The fact that regulatory enzymes, almost without exception, are polymeric, argues strongly for the role of subunit interaction in the cooperativity. The potential for achieving sophisticated control is undoubtedly greater with a polymeric, than with a monomeric enzyme. However, most of prevailing models for explaining the cooperative effects of subunits are based on ligand-promoted conformational equilibria. While they adequately describe the change of enzymatic activity in response to metabolite concentration, they fail to link intersubunit cooperation to the catalytic mechanism *per se*.

Concerted and Sequential Models

Two major models, the concerted model of Monod *et al.* (1965), and the sequential model of Koshland *et al.* (1966), have been proposed to explain the cooperative binding of ligands to multisubunit proteins. In the concerted model, Monod *et al.* assumed that an enzyme having identical and noninteracting subunits arranged in a symmetrical manner can exist in two conformational states, T and R, with different ligand binding affinities. A key feature of the Monod model is the conservation of symmetry, i.e., the T and R transition is a

concerted one such that all subunits in a given state are equivalent. The cooperative phenomenon, however, arises from the preexisting $T \rightleftharpoons R$ equilibrium in an apparent cooperativity. This two-state Monod model can be extended to accommodate more complicated situations. For instance, the original Monod model based on rapid equilibria cannot generate negative cooperativity. However, a proposed pseudo-conservative transition has been demonstrated as a modified Monod model that allows the two-state model to accommodate both positive and negative cooperativities (Viratelle and Seydoux, 1975). The sequential model of Koshland *et al.* is based on the induced-fit theory. Mathematically, this model is similar to those developed by Adair (Adair, 1925) and Pauling (Pauling, 1935). In this case the subunits are initially identical and binding of a ligand to one subunit affects the subsequent binding of ligands to the remaining subunits. This model is often referred to as the sequential model as opposed to the concerted model of Monod *et al.* The sequential model can be readily adapted to the case where the subunits are initially nonidentical (preexisting asymmetry). Since the binding of a ligand to one subunit can either improve or impair the binding affinities for the remaining subunits, positive, negative, and 'mixed' cooperativities may result. Importantly, both concerted and sequential models have been successfully applied, for example, by Schachman's and Koshland's groups, to the analysis of cooperative systems (Huang *et al.*, 1982).

Water as Life's Aether

Water, representing about 70% of cell's weight, plays a vital role in sustaining all forms of life. Therefore many aspects of life are affected by the physical and chemical properties of water, and many of these properties are derived from different electronegativities of H and O atoms that make water a highly polar molecule. As a consequence, most water molecules are in contact with their neighboring molecules through hydrogen bonding with itself and with solutes (Liu *et al.*, 1996). The hydrogen bonds are rapidly broken and reformed, with an average lifetime of $\sim 10^{-12}$ s. The capability of hydrogen bonding and its polarity make water a highly interacting molecule, as well as an excellent solvent for polar solutes by weakening electrostatic forces and forming hydrogen bonds between polar molecules. However, this property of water also poses a problem for living cells because it weakens interactions between polar molecules. To overcome this problem, biochemical systems generate hydrophobic microenvironments to maintain polar interactions at their maximal strength and specificity where needed. Furthermore, since water binds strongly to itself, it induces self-aggregation of nonpolar molecules such as lipids in an aqueous medium. This capacity of water facilitates the formation of cellular membranes that define the boundaries of cells and their internal components.

Another unique property of water is that it can ionize into H^+ and OH^- where H^+ exists as hydronium ions, H_3O^+ , in aqueous medium. For simplicity H^+ is used instead of the actual species present. On average, 1 out of 10^7 water molecules is ionized in its pure liquid. In biochemistry the concentration of H^+ is expressed as pH, defined as $pH = -\log$

$[H^+]$, where $[H^+]$ is in units of molarity. Thus, the greater the acidity of a solution, the lower its pH. A pH 7.0 solution contains $[H^+] = 1.0 \times 10^{-7}$ M. Since the concentration of water is 55.5 M, it does not change much under most biological conditions. Thus, the equilibrium constant for water can be simplified to

$$K_w = [H^+][OH^-] = 1.0 \times 10^{-14} M^2 \quad [16]$$

at 25 °C. This indicates that the ionization of water at 25 °C is highly unfavorable since its ΔG^0 is 19.1 kcal mol⁻¹. However, the extent of water ionization can be altered by the presence of other species that can bind either H^+ or OH^- . These species include proteins, DNA, RNA as well as cellular metal ions. From the K_w expression, one can obtain the $[OH^-]$ in aqueous solution knowing the pH value. For example, if $[H^+]$ is 10^{-3} M, then $[OH^-] = 10^{-14}/10^{-3} = 10^{-11}$ M. In essence, $[H^+]$ and $[OH^-]$ exhibit a reciprocal relationship.

Acid-Base Reactions Play a Central Role in Most Biochemical Processes

The equilibrium constant for the ionization of a weak acid, HA, can be described as $K = ([H^+][A^-])/[HA]$. The pK of this acid is defined as $pK = -\log K$. Thus the pH of a solution can be calculated using the eqn [17], known as Henderson-Hasselbalch equation, if the molar ratio of A- to HA and the pK of HA is known. Conversely, the pK of an acid can be calculated if the molar ratio of A- to HA and the pH of the solution is known.

$$pH = pK + \log([A^-]/[HA]) \quad [17]$$

When a solution contains a weak acid-base conjugate pair, for example, acetic acid and acetate, it can serve as a buffer with the capacity to prevent a significant change in its pH due to the addition of a small quantity of either strong acid or base. In general, the best buffer capacity of a given buffer system occurs in a range of one pH unit on either side of its pK. Interestingly, cells and organisms maintain a specific and constant cytosolic pH to keep biomolecules in their optimal ionic state. Furthermore, a significant change in pH can potentially lead to protonation or deprotonation of key functional groups of biomacromolecules that cause disruption of their molecular structures and lead to harmful biological effects. Thus, nature has evolved to minimize pH changes in biological systems. To this end, biological systems make use of a number of weak acids as their buffer systems to maintain a relatively constant physiological pH, typically around pH 7.4. Since a buffer functions best close to its pK value, among the biological buffers, phosphoric acid, which exists primarily in a near equal mixture of $H_2PO_4^-$ and HPO_4^{2-} at about pH 7.4, plays a major role to maintain physiological pH. Consistent with this notion, inorganic phosphate is present at about 1 mM in blood for maintaining its pH at 7.4.

Noncovalent Interactions Play Key Roles in Mediating Functions of Biomacromolecules

Weak noncovalent interactions exert a decisive role in maintaining the structure and function of macromolecules,

although all biomacromolecules are formed mainly by covalently linked carbon bonds (bond energy $\sim 85 \text{ kcal mol}^{-1}$), and covalent interconversion of enzyme cascades, which possess an enormous capacity for signal and rate amplification, play important roles in regulating cell signaling and metabolism (Chock and Stadtman, 1996). Specifically, noncovalent interactions are involved in stabilizing the double helix structure of DNA, in orchestrating RNAs interactions to exert their transcriptional and translational regulation, and in the folding of proteins/enzymes into intricate three-dimensional structures to accommodate their enzymatic activities and substrate specificity. The four extensively utilized noncovalent interactions are electrostatic interactions, hydrogen bonding interactions, van der Waals interaction, and hydrophobic interactions. They differ in their nature of their interactions, bond strength and specificity as follows: (1) Electrostatic interactions, resulting from the Coulombic interaction between two opposite atomic charges located on two molecules. The energy of this interaction is governed by Coulomb's law, namely, $E = kq_1q_2/Dr$, where E is the energy, q_1 and q_2 are the charges on the two atoms, at r angstroms apart, D is the dielectric constant of the medium and k is a proportionality constant, which has a value of 332 when the energy is expressed in kcal mol^{-1} . By convention, an attractive interaction would have a negative energy. In an aqueous medium, $D=80$, when $r=3 \text{ \AA}$ between the two ions bear single opposite charges, the electrostatic interaction energy is $-1.4 \text{ kcal mol}^{-1}$. However, this interaction is significantly strengthened when it occurs on the protein surface ($\sim -4.8 \text{ kcal mol}^{-1}$) or in the interior of the protein ($\sim -60 \text{ kcal mol}^{-1}$) due to changes in the dielectric constant of the reaction medium. (2) Hydrogen bonds, where the hydrogen atom is partially shared by two electronegative atoms such as nitrogen or oxygen. This leads to a favorable dipole-dipole interaction. The strength of this interaction falls off quickly with distance, or when the angle between the dipole is far from linear. Hydrogen bonds between the protein back bone amide nitrogen and carboxyl oxygen play a major role in stabilizing the α -helix and β -sheet structure of proteins, as well as determining the conformation of proteins. The energy for hydrogen bonds is in the range of $\sim 1\text{--}5 \text{ kcal mol}^{-1}$. (3) van der Waals interactions, derived from weak attractions that occur between atoms in close proximity to each other. The basis of these interactions is the attraction of the positively charged nucleus and negatively charged electron clouds between different atoms. For atoms commonly found in biological molecules, van der Waals attractions are optimal at distances between 3 and 4 $\text{\AA}$, and become negligible beyond 5 $\text{\AA}$. The van der Waals repulsion prevents atoms getting much closer than $\sim 3 \text{ \AA}$ apart. The energy associated with the van der Waals interaction is $\sim 0.5\text{--}1 \text{ kcal mol}^{-1}$, depending on the van der Waals distance. (4) Hydrophobic interactions are due to the tendency of nonpolar molecules to stick together in an aqueous medium. Nonpolar molecules do not easily dissolve in water, in part due to their inability to participate in hydrogen bonding or ionic interactions with water and to restructure the hydrogen bonding among water molecules. The poor solubility is governed by a large entropy reduction. A model, generally known as the iceberg model, has been proposed to provide a molecular interpretation for the large entropy loss to the structural

enhancement of water molecules near the vicinity of a nonpolar solute. However, the validity of this model is still a matter for debate, in view of recent experimental and theoretical analysis that reveals that water does not form a structure around the nonpolar solute at room temperature and a large part of negative entropy of solvation can be attributed to the small size of water molecules such that the nonpolar solute can interact with high number of water molecules and leads to a large decrease in entropy. For details on this issue, please see reference (Blokzijl and Engberts, 1993; Lee, 1985). Nevertheless, hydrophobic interactions are well accepted as the dominant energetic factor to mediate the formation of protein tertiary structure, enzyme-substrate/effector interaction and the stability of biological membranes.

While each of these noncovalent interactions is relatively weak, collectively they determine the biological structures and functions of proteins, nucleic acids, lipids, and carbohydrates. It is essential to note that every ion in an aqueous medium is surrounded by a shell of oriented water molecules maintained by the attraction of water dipoles to the charged ion. Thus, hydration of ions has a major influence on all aspects of electrostatic interactions for which the strength of acids and bases plays an important role. Since proteins contain multiple acidic and basic groups, it is reasonable to expect both the conformation and activity of enzymes to be altered as a function of the concentration of hydrogen ions.

Effect of Molecular Crowding in Living Cells

The biochemical and biophysical principles discussed in preceding sections were derived mainly from *in vitro* studies using pure reactants, often small molecules, or in relatively low concentrations, for example, less than 1 mg ml^{-1} of total macromolecule such as protein, nucleic acids, or polysaccharides. However, all cells contain various biomacromolecules at high concentration (Hoppert and Mayer, 1999). Biochemical reactions in living cells occur in media crowded with other soluble or structured macromolecules, resulting in nonspecific interactions between individual macromolecules and their immediate surroundings in the cytosol. These background interactions lead to three different phenomena: (1) macromolecular crowding, attributed to volume excluded by one soluble macromolecule to another; (2) macromolecular confinement, attributed to steric-repulsive interactions between the macromolecule of interest and its static boundaries; and (3) macromolecular adsorption, due to reversible association of a macromolecule to the surface of a nearby fiber or membrane (Minton, 2006). Nonspecific interactions may either be repulsive, leading to preferential size and shape dependent exclusion, or attractive, leading to nonspecific binding or adsorption. Predominantly repulsive background interactions tend to enhance the rate and extent of macromolecular association in solution, while predominantly attractive background interactions tend to enhance the tendency of macromolecules to cluster nonspecifically or adsorb onto surfaces. However, in a complex and heterogeneous medium of the cytoplasm, it is a challenge to discern whether the locally dominant background interactions are likely to be

attractive or repulsive and to identify their effects on any specific reaction.

Molecular crowding, in principle, can markedly slow down the diffusion rate. Consequently crowding plays a role in all biological processes mediated by noncovalent associations or conformational changes of the macromolecules, such as those involved in the synthesis of nucleic acids and proteins, intermediary metabolism and cell signaling, as well as the functioning of dynamic motile systems. In general, macromolecular crowding nonspecifically enhances reactions leading to the reduction of total excluded volume, independent of hydrogen bondings, van der Waals forces or charges. These reactions include the formation of macromolecular complexes in the medium, binding of macromolecules to surface binding sites, formation of insoluble aggregates, as well as compaction or folding of proteins. Simple statistical-thermodynamic modeling studies reveal that the 'passive crowding macromolecules' could exert order-of-magnitude or greater changes in both the rates and equilibria of numerous reactions tested. To this end, one should also recognize that system studies via simulation are still models instead of the real thing. Not all idiosyncratic details of the model system are of general value for understanding the real cellular system. Biological systems are more complex than theoretical or *in vitro* experimental studies because of enhanced heterogeneity and the presence of nonspecific repulsive and attractive intermolecular interactions in addition to volume exclusion. Model studies also show that the magnitude of the effects is strongly dependent on the relative sizes and shapes of the concentrated crowding species used and on the nature of the macromolecular reactants and products. However, to date, the results obtained via model simulation studies have provided important new insights for understanding the subject. In view of the complexity and heterogeneity of the intracellular fluids, results from simplified model studies can only partially address the complex problems encountered with the *in vivo* system (Zhou *et al.*, 2008; Ellis, 2001).

The densely packed environment in the cytosol appears to impede the folding of relatively large polypeptides since their diffusion rates would be more drastically reduced relative to those of smaller polypeptides. Furthermore, the presence of a large number of crowding macromolecules would increase the probability for a newly synthesized polypeptide to interact with other macromolecules before it can properly fold. To overcome these problems, nature makes use of a class of molecular chaperones as well as a number of protein disulfide isomerases to facilitate proper folding of nascent proteins, including those mediated by cysteine disulfide bond formation, to yield functional proteins. As a result, proteins are found to be folded very efficiently when synthesized inside the cell. Anfinsen showed that it took several hours for ribonuclease-A to fold in the test tube, a rate much slower than the rate at which functional ribonuclease-A is produced in cells (about 2 min.). A similar rationale was adopted in cell signaling. To facilitate cell signaling processes inside crowded cytosols, scaffold or anchorage proteins are adopted to generate signalsomes to process cell signaling. To this end, formation of intracellular Dishevelled-based signalsomes has been demonstrated to occur during the activation of Wnt signaling (Yokoyama *et al.*, 2010).

Concluding Remarks

To understand the molecular mechanisms of biological processes through which living cells stay alive, grow, reproduce, and evolve, we must understand how fundamental chemical and physical principles govern these reactions. In this article, a brief discussion is provided of (1) the chemical nature of cellular macromolecules, (2) the roles of water molecules and noncovalent interactions in stabilizing the reactive conformations of these macromolecules, (3) thermodynamic principles which determine whether reactions can occur spontaneously, and (4) principles of reaction kinetics in maintaining reaction processes at dynamic steady states, away from reaction equilibrium. For a more in-depth understanding of these principles, readers are referred to additional literature (Edsall and Gutfreund, 1983; Alberty, 2003; Moore and Pearson, 1981; Purich, 2010; Connors, 1990; Zhou *et al.*, 2008; Ellis, 2001; Yokoyama *et al.*, 2010; Atkins and de Paula, 2012). Finally, the potential effects of molecular crowding inside the cell were discussed in terms of principles derived from *in vitro* studies with dilute purified macromolecules and high substrate concentrations.

Introduction

Biological Catalysts

Enzymes and ribozymes are essential to life. These macromolecules catalyze a vast array of chemical reactions that, in the absence of the biocatalyst, would take place at very low intrinsic and uncoordinated rates incompatible with life. Biocatalysts control the complex chemistry of thousands of life processes through acceleration and regulation of the rates of virtually every chemical reaction important to life. Prevention of unwanted chemical reactions relies on keeping reactive molecules apart through compartmentalization or on binding of the chemicals to macromolecules that stabilize their desired forms.

The magnitudes of rate enhancement brought about by biocatalysts approach astronomical values. For example, at 25 °C uncatalyzed hydrolysis of phosphodiester linkages between nucleotides in DNA proceeds with a half-life ($t_{1/2}$) of 30 000 000 years (Schroeder *et al.*, 2006). The refractory nature of phosphodiester linkages between nucleotides in DNA permits preservation of genetic information for hundreds of thousands, if not millions, of years. Yet biological processes at times require certain phosphodiester linkages in DNA to be cleaved. Staphylococcal nuclease, one of the enzymes that catalyzes DNA-hydrolysis, functions with a turnover number of 95 s^{-1} , corresponding to a $t_{1/2}$ of 7 ms. This enormous rate difference, or enzymatic enhancement factor, of 1.4×10^{17} corresponds to typical values for enzymes, and is neither the minimum nor the maximum. Nonenzymatic counterparts of certain enzymatic reactions are too slow to measure, so that only lower limits of rate enhancements for those reactions can be estimated.

In life, individual biocatalytic rates must be coordinated, and they must change under varying cellular developmental, metabolic, and environmental conditions. Coordination arises through several mechanisms. In genetic regulation, the relative amounts of enzymes produced by gene transcription and translation can be regulated to produce the appropriate amounts of metabolically or developmentally related enzymes. In metabolic control, metabolites regulate the activities of key enzymes through allosteric effects upon binding to regulatory sites of key enzymes. For example, in end-product inhibition the enzyme catalyzing the first committed step in a metabolic or biosynthetic pathway is often inhibited by the end product of that pathway, thereby shutting it down once the end product rises to an optimal concentration. The intra-organellar microenvironments in cells can activate or inhibit certain enzymes. For example, the acidic environments in lysosomes activate pH-dependent proteolytic enzymes. Posttranslational modifications of enzymes such as reversible phosphorylation of specific amino acid side chains are also important control mechanisms. These regulatory processes orchestrate the best balance of enzymatic activities to support the life of an organism.

Enzymes

Composition

Most biocatalysts are proteins known as enzymes. As proteins, they are linear polypeptides composed of the 20 common α -amino acids (Table 1) linked by peptide amide bonds. They range in molecular weights from ~ 8000 to $> 150\,000$. The polypeptide chains of enzymes are folded into definite globular structures, many of which have been determined by X-ray crystallography or by nuclear magnetic resonance spectroscopy. The folded structures include secondary, periodic structures of α -helix and β -sheet segments, together with non-periodic loop-segments. More than 5000 'different' enzymes are currently covered by the Enzyme Commission, and more are discovered each year.

Figure 1 depicts the protein chain fold of homodimeric enolase, showing the α -helical, β -sheet segments, and loop segments. Enolase catalyzes the dehydration of 2-phosphoglycerate to phosphoenolpyruvate. The chain fold of the core of enolase is widely known as the TIM barrel, named for the first enzyme found to display this fold, triosephosphate isomerase. It is also known as the β -barrel. While many protein chain folds are known, the TIM barrel is highly versatile and serves many purposes in enzymology. About 10% of known enzyme structures are based on the TIM barrel.

Enzymes exist as single polypeptides or as aggregates of identical or different subunits. Multisubunit enzymes can be dimers, trimers, tetramers, pentamers, hexamers, etc. of identical subunits. Some enzymes have nonidentical subunits, in which the subunits are either different enzymes catalyzing related reactions or regulatory entities that control catalytic rates. The largest aggregated enzymes include several enzymes acting in concert to catalyze processive reactions. Examples include α -ketoacid dehydrogenase complexes, which contain three enzymes plus regulatory subunits and are approximately the size of ribosomes. Other examples are the fatty acid synthase complexes, which contain six enzymes and produce fatty acids from acetyl coenzyme A in assembly-line fashion. Polyketide synthases and nonribosomal polypeptide synthases are analogous, aggregated enzymes that produce antibiotics such as erythromycin and tyrocidine.

Kinetics

Activities of typical enzymes can be measured as initial rates under specified conditions. Dependence of initial rates produced by a fixed amount of an enzyme, acting on varying concentrations of the substrate, produce hyperbolic plots of rate against substrate concentrations. The plots are consistent with the Briggs–Haldane revision of the Michaelis–Menten kinetic mechanism and the corresponding rate law, eqns [1] and [2a], where E, S, and P represent enzyme, substrate, and product. In eqn [2a], $K_m = (k_2 + k_3)/k_1$ and $V_m = k_3[E_0]$. Note

that the dissociation constant of the substrate, K_d , is defined as k_2/k_1 .

$$v = \frac{V_m[S]}{K_m + [S]} \quad [2a]$$

$$\frac{1}{v} = \frac{1}{V_m} + \frac{K_m}{V_m} \cdot \frac{1}{[S]} \quad [2b]$$

Equation [2a] predicts that when $[S] \ll K_m$, the rate is proportional to $[S]$, and when $[S] \gg K_m$ the rate approaches V_m , the maximum as shown in **Figure 2(a)**. The maximum rate in any experiment is proportional to the enzyme concentration $[E_0]$. The reciprocal form of eqn [2a] (eqn [2b]; **Figure 2(b)**) predicts a linear relationship between $1/v$ and $1/[S]$ having an intercept on the ordinate of $1/V_m$ and a slope of K_m/V_m . Manual fitting of kinetic data is facilitated by the linear form, whereas computer programs can be used to fit data directly to eqn [2a].

Equation [1] refers to an enzyme with one substrate and one product. Many complex enzymes act on two, three, or more substrates. In such cases, more complicated kinetic mechanisms apply, and the rate laws are correspondingly more complex, with more terms in the numerators and denominators than in eqn [2a]. However, for enzymes not subject to

special regulatory effects, the complex equations are reducible to the form of the Michaelis–Menten equation when all co-substrates are held constant and only one is varied. In these cases, the measured parameters are apparent values V_m^{app} and K_m^{app} , from which limiting values can be obtained by varying the concentrations of co-substrates in further analysis.

A full discussion of multisubstrate kinetics lies beyond the scope of this article. However, the complications can be appreciated by considering the general patterns for two-substrate, two-product reactions, the case of substrates A and B reacting to form products C and D. The most common case is that of eqn [3], where the two substrates become associated with the enzyme in stepwise fashion, either in random order or in compulsory order, to form the ternary complex E.A.B in eqn [3]. The substrates react within the ternary complex to form the products C and D, which dissociate in either random or ordered steps. Kinetic mechanisms of this type are known as sequential mechanisms. The rate eqn [4] describes the initial rate kinetics of the rapid equilibrium version of the sequential mechanism.

$$v = \frac{V_m[A][B]}{K_{iA}K_B + K_B[A] + K_A[B] + [A][B]} \quad [4]$$

In eqn [4], $K_{iA} = (E)(A)/(EA)$ is the dissociation constant of A, $K_B = (EA)(B)/(EAB)$, and $K_A = (EB)(A)/(EAB)$. In an initial rate

Figure 1 The structure and mechanism of enolase. (a) Shows a cartoon representation of the molecular structure of homodimeric enolase from baker's yeast. Secondary structural elements are color coded in one subunit of the dimer: cyan α -helical; red β -sheet; wheat loops. The tightly bound Mg^{2+} in each subunit appears as a sphere. The eight-stranded barrel is atypical in having one strand pointed in the opposite direction. The structure was obtained from PDB file 1ONE (Larsen *et al.*, 1996). (b) Shows the stepwise mechanism by which enolase catalyzes the dehydration of (*R*)-2-phosphoglycerate, showing the acid–base catalysis by Glu211 and Lys345 and the intermediate formation of the enolate (Poyner *et al.*, 1996).

study with $[\text{B}]$ held constant and $[\text{A}]$ varied, the data can be treated as in the one-substrate case.

Another kinetic mechanism frequently observed is that described in eqns [5a] and [5b]. In this mechanism substrate A binds and reacts chemically with the active site, transforming it in a distinctive way to a form designated as E-x and releasing product C. The transformation can frequently be ligation of a group ($-\text{x}$) from the substrate to the enzyme. Alternatively, reducing equivalents can be transferred to a cofactor (see below) at the active site. The chemically modified enzyme then reacts with the second substrate B, transferring the group ($-\text{x}$) to form product D. Kinetic schemes of this type are frequently

called ping pong mechanisms.

$$v = \frac{V_m [\text{A}][\text{B}]}{K_A [\text{B}] + K_B [\text{A}] + [\text{A}][\text{B}]} \quad [6]$$

The rate equation for the ping pong mechanism (eqn [6]) lacks the constant term, $K_A K_B$, in the denominator of eqn [4].

Figure 2 Reaction kinetics for an enzymatic reaction having a single substrate and single product. (a) Shows the direct plot of velocity, v , versus substrate concentration, $[S]$, according to eqn [2a] (see text) using V_m of 5 (arbitrary units) and a K_m of 0.25 (arbitrary units). (b) Shows the same data plotted in double reciprocal form according to eqn [2b], where the ordinate intercept is $1/V_m$ and the slope is K_m/V_m .

Double reciprocal plots of data, $1/v$ versus $1/[B]$ at different concentrations of A appear as parallel lines, having a common slope and different intercepts. A particular property of this mechanism is that the intermediate E-x can be generated, isolated, and chemically characterized by excluding substrate B. This provides chemical information about the reaction mechanism and the function of the active site. A compilation of kinetic expressions and details of their applications are available (Segel, 1993; Cook and Cleland, 2007).

Whether a multisubstrate enzyme functions by a sequential or ping pong mechanism depends on several factors, including the type of chemical reaction. Comparisons of the mechanisms of chemically similar phosphotransfer reaction, where -x is a phosphoryl or nucleotidyl group, have led to the principle of economy in the evolution of binding sites as a governing factor (Frey, 1992). The central fact that phosphotransferring enzymes function by ping pong mechanisms when the phospho-accepting substrates are sterically and electrostatically related inspired the postulation of this principle. The kinetic and chemical mechanisms of adenylate kinase (AK) and nucleoside diphosphate kinase (NucDipK) exemplify this principle.

AK functions by a sequential mechanism, whereas NucDipK functions by a ping pong mechanism, in which -x is the phosphoryl group (PO_3) bonded to a histidine residue. Overall, the reactions are chemically similar, phosphoryl transfer between phosphogroups. In the action of NucDipK, the sterically and electrostatically similar phosphoacceptors, NDP going forward and ADP in reverse, occupy the same binding site. Thus, the enzyme needs just one binding site, incorporating the phospho-accepting histidine residue.

In the reaction of AK two binding sites are required. The phosphoacceptors, AMP going forward and ADP in reverse, are sterically and electrostatically incompatible with a single binding site. Therefore, AK has a phosphodonor site and a phosphoacceptor sites. This allows ternary complex formation (E.ATP.AMP) and avoids the need for an E- PO_3 to bind the phosphoryl group during the interchange of phosphoacceptors.

The principle of economy in the evolution of binding sites appears to govern a number of other classes of enzymatic reaction mechanisms, where single binding sites function in double-duty fashion (Frey, 1992; Grove et al., 2011).

Substrate Selectivity

The specificity of enzymes for their substrates is frequently overstated. 'Highly selective' is a more apt description of their capacity to discriminate among similar molecules. Most enzymes will act on molecules related to their natural substrates, but at lower rates. An enzyme often functions on alternative substrates at 1/100th or 1/1000th the rate for the natural substrate, and such a rate could still correspond to a rate enhancement of, for example, 10^8 – 10^{12} . Metabolism of drugs and other xenobiotic compounds typically exploits the capacity of enzymes to function with alternative substrates.

Cooperativity and Allosteric Regulation

In classical behavior, each active site in a multi-subunit enzyme acts independently of neighboring subunits. Multi-subunit enzymes may also exhibit cooperative behavior among subunits in binding of substrates and in catalysis such that binding of a substrate to one subunit influences the subsequent binding of substrate to neighboring subunits. This cooperative behavior, either negative or positive, may also be modulated by effector molecules that bind to distinct regulatory sites in the oligomer termed allosteric sites.

Cooperativity and associated allosteric control provide a means to ‘fine tuning’ of catalytic activity to meet changing demands of cells and organisms.

Chemical Mechanisms

Rates of chemical reactions can be described in terms of transition state theory also known as absolute reaction rate theory. This formalism accounts for the temperature dependence of thermally activated chemical reactions. Descriptions of photochemical and electron transfer reactions are slightly different. For thermally activated reactions, a tiny fraction of the reactant(s) (determined by the Boltzmann distribution law) initially in their ground vibrational state(s), acquire from their surrounding, sufficient excess internal (vibrational) energy to ascend transiently to a high energy state, called the transition state or activated complex. In a reaction coordinate diagram, the transition state is located at the apex – a position at which the molecule or complex can descend either in the reverse direction to reactant(s) or in the forward direction to product(s). **Figure 3** illustrates the relevant energies for the reaction of a substrate S to a product P by way of $S^\ddagger$, the transition state or activated complex. The activation energy for the spontaneous reaction is E_a^S .

In the corresponding enzymatic reaction, **Figure 3** shows the energy of activation E_a^{ES} for the $E.S$ complex. The ground state for the $E.S$ complex is shown as slightly lower than for the spontaneous reaction. The difference $E_a^S - E_a^{ES} = \Delta E_a$ represents the decrease in activation energy for the enzymatic relative to the nonenzymatic reaction. This difference represents the magnitude of enzymatic catalysis, or the rate enhancement. Because activation energies have an inverse exponential influence on rates (Boltzmann distribution of activated complexes)

Figure 3 Relative potential energy curves along the reaction path for chemical reactions. The upper curve shows the potential energy along a reaction coordinate for a nonenzymatic reaction, showing the energy of the transition state or activated complex $S^\ddagger$ at the maximum. The activation energy is E_a^S . The lower curve depicts the potential-reaction coordinate for the same reaction catalyzed by an enzyme. The activation energy is E_a^{ES} .

modest changes in ΔE_a translate to large changes in rate. Although kinetic measurements can detect small changes in the activation energy, the general rule is that the smallest free energy difference that can be conceptualized is ~ 1 kcal, which corresponds to a rate difference of approximately sevenfold. When functioning as catalysts at concentrations much less than those of their respective substrates, enzymes do not alter the thermodynamic equilibria of the reactions that they catalyze but rather alter only the rate at which equilibrium is attained.

Rate enhancement by enzymes begins with the binding of substrate(s) at the pre-organized active site, where the substrate(s) is or are bound in close proximity to catalytic groups within the active site. For enzymes that do not require a cofactor or coenzyme, the catalytic groups are one or more of the reactive amino acid side chains in the right-hand column of **Table 1**. Each of these groups, with the exception of cystine, displays both acid/base and nucleophilic reactivities. In different enzymes, each group functions either as a nucleophilic catalyst or as an acid/base catalyst. For example, in the reaction of enolase (**Figure 1**) the elimination of water from 2-phosphoglycerate is facilitated by acid–base catalysis by Lys345 and Glu211. In the action of NucDipK, phosphotransfer is facilitated by a histidine residue and nucleophilic catalysis (see above).

Transition State Analogs and Catalytic Antibodies

A prediction of transition state theory is that a substantial part of the catalytic rate enhancement of enzymes is due to a tight binding of the transition state of the respective reaction. Molecules that mimic the transition state of an enzyme-catalyzed reaction (transition state analogs) are expected to bind to the active site with high affinity (Wolfenden, 1972). A substantial fraction of drugs are molecules that bind to enzymes in place of the normal substrates and thereby inhibit the activity of the target enzyme. The transition state analog approach to design of selective tight binding inhibitors of target enzymes has been practiced with substantial success (Schramm, 2007).

Another practical application of transition state mimics is in the generation of antibodies that have catalytic activities for specific reactions. Antibodies arise in the blood serum of animals in the process of immunization, which entails exposure to foreign proteins, antigens, for example, the coat proteins of bacteria or viruses. Antibodies are produced in specialized mammalian cells and released into the blood stream. They recognize and mark antigen molecules for destruction by binding them very tightly ($K_d \sim 10^{-14}$ M). Antibodies are large protein molecules, in which a smaller domain, the Fab fragment, encompasses the antigen-binding site. An antigen-binding site recognizes and binds segments known as epitopes of antigenic proteins. An epitope might be a decapeptidyl unit within a foreign protein. However, antigen-binding sites are not limited to polypeptides as ligands and may bind other molecules as well. Thus, immunization of an animal with a foreign protein chemically linked to a dinitrophenyl (DNP) group, a hapten, will lead to the production of anti-DNP antibodies. The tight binding between an antigen and an antibody can be exploited to create a catalytic antibody. In this method, a molecule embodying a stable,

structural analog of the transition state for a desired reaction can be used as a hapten to elicit the production of an antibody that binds the transition state analog tightly. In theory, such tight binding should lead to catalysis of a reaction with a transition state structurally similar to that of the hapten. The antibody is then a catalytic antibody. The emergence of methods to generate homogeneous populations (clones) of antibody molecules has enabled the production and characterization of monoclonal antibodies having homogeneous antigen-binding sites and properties (Shokat and Schultz, 1990). Thus, haptens mimicking transition states of chemical reactions have been used to generate monoclonal antibodies having high affinities for these transition state mimics (Padioulet-Lefevre *et al.*, 2014). Rate enhancements achieved with catalytic antibodies are frequently modest (10^2 – 10^4); however, rate enhancements of 10^{10} have been reported (Xu *et al.*, 2004). Several classes of chemical reactions have been investigated using the catalytic antibody approach.

Coenzymes and Cofactors

Enzymatic reactions are so diverse that the side-chain functional groups are not chemically sufficient, by themselves, to catalyze all enzymatic reactions. Processes such as electron transfer, oxidation/reduction, oxygenation, decarboxylation of α -amino acids and α -ketoacids, dehydrogenation, complex group transfers, and free radical reactions, among others, require special chemistry. Thus, the activities of many enzymes require co-catalysts known as cofactors or coenzymes.

The coenzymes and cofactors include metal ions, activated vitamins, and small organic molecules shown in Figure 4(a). These molecules exhibit special chemical properties that are essential in some enzymatic reactions. A few of the co-catalysts, including TTQ, TPQ, and MIO arise from posttranslational modifications of amino acid side chains of the enzyme itself. Figure 4(a) includes activated forms of vitamins such as niacin (NAD^+), thiamine (ThDP), riboflavin (FAD, FMN), vitamin B₆ (PLP), pantothenic acid (phosphopantetheine), and biotin. The vitamin coenzymes play essential roles in many oxidation–reduction, decarboxylation, carboxylation, racemization, elimination, and carbon–carbon bond cleavage reactions. The npn-vitamin derived cofactors PQQ, TTQ, TPQ, lipoamide, and MIO play essential chemical roles in dehydrogenases and oxidoreductases.

Figure 4(b) shows the structures of a number of metallic cofactors, including heme, which functions in oxygenation and electron transfer reactions. AdoCbl, the coenzyme form of vitamin B₁₂, and AdoMet-[4Fe-4S] function similarly to initiate free radical chemistry in many biological reactions. Iron–sulfur clusters are important in many electron transfer roles. The oxo-Fe₂ complexes facilitate oxygenation and dehydrogenation in several enzymes. Molybdopterin and tungstopterin complexes are essential in a number of oxidases and reductases. In dinitrogenase, the FeMo coenzyme reduces N₂ to 2NH₃ in an ATP-dependent process. In certain organisms, vanadium replaces molybdenum whenever the latter is unavailable. The nickel complex F₄₃₀ anchors the reductive process of methanogenesis.

Metal ions involved in enzymatic catalysis include magnesium, iron, copper, manganese, zinc, cobalt, calcium, nickel,

and potassium. Mononuclear complexes of iron or copper in many enzymes react with O₂ and introduce hydroxyl groups into organic substrate molecules. In enolase two Mg²⁺ ligate the carboxylate group of 2-phosphoglycerate. The resultant positive charge increases the acidity 2-phosphoglycerate and allows Lys345 to abstract C2(H) to give the enolate intermediate in the dehydration reaction (Larsen *et al.*, 1996). Mg²⁺ complexes of nucleoside di- and triphosphates are the actual substrates of the multitude of reactions of enzymes operating on these molecules. Metalloproteases use either mononuclear or dinuclear complexes of Zn²⁺ or Co²⁺ in catalyzing hydrolysis of peptide bonds. Many phosphatases use ions of metals such as Zn, Mg, Ca, Fe singly or in combinations in their hydrolytic reactions.

Ribozymes

Ribozymes are RNA enzymes. They catalyze the chemical processing of RNA and of the information contained within the nucleotide sequences of RNA. Ribozyme function includes the excision of introns from the initial mRNA transcripts of genes encoded by DNA. Ribozyme function also includes peptide bond formation – the final step in the translation of DNA in protein biosynthesis.

Hammerhead

The ribozymes range in size from about 50 ribonucleotides to the species of RNA in the small and large subunits of the ribosome that comprise up to a few thousand ribonucleotides. The hammerhead ribozyme belongs to the small ribozyme family. It catalyzes the self-cleavage of a precursor RNA and the joining of resultant RNA fragments to produce the hammerhead ribozyme. The name hammerhead arises from the appearance of an earlier secondary structural representation that resembled the outline of a hammerhead shark. Figure 5(a) shows the secondary structure of a generic hammerhead ribozyme. The loops and helices fold into a tertiary structure. The hammerhead functions in rolling circle replication.

The hammerhead, like many ribozymes, catalyzes the cleavage of specific 3',5'-phosphodiester linkages within RNA. The initial cleavage produces smaller species of RNA in which one product contains, 2',3'-cyclic-CMP at the 3'-end, as shown in Figure 5(b). The other cleavage product has a 5'-OH end. The reaction proceeds with a turnover number of $\sim 1 \text{ min}^{-1}$. As indicated in Figure 5(b), the reaction is reversible because the 2',3'-cyclic-phosphodiester is an activated species that reacts favorably with the 5'-OH group to generate a 3',5'-phosphodiester. This reversibility allows rejoining activity in RNA processing.

The RNA cleavage reaction in Figure 5(b) involves an acid, A–H, to donate a proton to the 5'-O leaving group and a base, :B, to abstract a proton from the C2'(OH) group of the cytidyl nucleotide. This mechanism takes advantage of the most biologically and chemically significant property of RNA, the susceptibility of RNA to base catalyzed hydrolysis. The hydroxide ion alone is sufficient to cleave RNA by abstraction of the proton from C2'(OH). Even the low concentration of hydroxide in neutral solutions (10^{-7} M) makes RNA too unstable to serve as the repository of genetic information, and

Small arrows indicate chain connectivity. Solid lines indicate Watson–Crick pairs. Dashed lines indicate non Watson–Crick tertiary interactions. (b) Shows the chemistry of the strand cleavage catalyzed by the hammerhead ribozyme, where A–H represents an acid and :B represents a base.

this process also contributes to the high mutability of the RNA genome in RNA viruses. In ribozymes, acid and base groups within the structure accelerate the cleavage. In the hammerhead, G12 and G8 are believed to function as acid and base. Other small ribozymes function similarly to the hammerhead.

Self-Splicing Introns

Ribozymes also include the self-splicing introns in mRNA transcripts. These are much larger than small ribozymes and carry out the essential function of excising introns from transcribed mRNA prior to translation in protein biosynthesis. The essential chemistry is that shown in Figure 5(b). The intron internally cleaves itself at each end, forming two 2',3'-cyclic-nucleotide ends and two 5'-OH ends. Cleavages are sequential and not simultaneous, but overall they lead to a 2',3'-cyclic nucleotide at the 3'-terminus of one exon, and a 5'-OH at the 5'-end of the neighboring exon. Then, the reversibility shown in Figure 5(b) allows these two ends to anneal. The intron itself can also anneal to a circular structure. The overall process is highly ordered and proceeds with complex tertiary structural rearrangements.

RNaseP

RNaseP is a ribonucleoprotein, in which the RNA component catalyzes the hydrolysis of RNA. The mechanism of 3',5'-phosphodiester cleavage is similar to Figure 5(b), but the 2',3'-phosphodiester product is further cleaved by water to the phosphomonoester. This process is analogous to the mechanism by which the protein enzyme ribonuclease catalyzes the hydrolysis of RNA. This ribozyme functions catalytically, like the protein enzyme.

The Ribosome

Translation of a mature mRNA produces a polypeptide chain that folds into a protein. The protein is either functional or undergoes posttranslational modification to become functional. In most cells, translation requires 20 amino acids, 20 aminoacyl-tRNA synthetase enzymes, 20 species of tRNA, ancillary protein based factors, and the ribosome. The ribosome catalyzes the final step of peptide bond formation. The process for a single amino acid is illustrated for alanine in eqns [9] and [10]. Alanyl-tRNA synthetase catalyzes the reactions shown in eqns [9a] and [9b], activating alanine for peptide bond for-

mation by initially forming alanyl adenylate (eqn [9a]), a carboxylic-phosphoric anhydride. In the second step, eqn [9b], alanyl adenylate reacts with the 2'-OH group of alanyl-tRNA (HO-tRNA^{Ala}) to form alanyl-tRNA^{Ala} and releasing AMP. The activated alanyl group in alanyl-tRNA^{Ala} is selected by the complex of mRNA-ribosome to react with the amino-terminal end of a growing polypeptide chain extending it and releasing HO-tRNA^{Ala}. The complementation of the anticodon in the tRNA of alanyl-tRNA^{Ala} with the codon for Ala in mRNA governs the selection alanyl-tRNA^{Ala} in eqn [10], while the ribosome catalyzes the chemistry in eqn [10]. The codons in mRNA govern the selection of the other nineteen species of aminoacyl-tRNA^{AA} to generate an accurate, translated amino acid sequence.

A ribosome consists of small and large species of ribosomal RNA (rRNA), as well as more than 20 protein subunits that stabilize the structure. The rRNA functions as a ribozyme (Cech, 2000) in catalyzing polypeptide biosynthesis by step-wise transfer of aminoacyl groups from the 20 species of aminoacyl-tRNA to the amino-terminal end of the growing polypeptide chain in the exact order specified by the codons in mature mRNA. This word picture is fully supported by the structure of the 70 S ribosome (Selmer *et al.*, 2006).

Glossary

Base-pairing The interaction between nucleobases responsible for the specificity of nucleic acid strand binding to other nucleic acid strands. Base-pairing occurs between adenine and thymine or cytosine with guanine in DNA; uridine replaces thymine in RNA and is base-paired with adenine.

Bridge amplification A method of preparing a polony based on the ligation of two adapter sequences surrounding a library insert. The adapter insert will hybridize to a oligonucleotide on a surface in flow cell. The adapter serves as primary for the synthesis of a daughter strand which will hybridize to another oligonucleotide via the second adapter which contains a cleavage site. Denaturation will remove the parent strand leaving the daughter strand which can then be amplified to yield a polony.

cDNA A single-stranded DNA complementary to an RNA synthesized *in vitro* by reverse transcription using a DNA polymerase usually obtained from a retrovirus.

Contig A major sequence of DNA which has been assembled from the sequences of many smaller DNA fragments; assumed to be a contraction of contiguous.

DNA distortions A conformational change in the regulator helical structure of DNA which can result from a chemical inserting into the helical structure, a process referred to as intercalation.

Hyperchromicity An increase in optical absorbance such as that seen with the denaturation of DNA.

Library A collection of cloned fragments which represent the genome. DNA sequence is obtained from fragments obtained from the library.

Long read A sequence of 500–1000 bases.

Long-noncoding RNA Large RNA molecules which are mostly bound to protein and serve a regulatory function.

Long read A sequence of 500–1000 bases.

MicroRNA Small RNA molecules which can modulate gene expression by influencing mRNA stability functioning as small interfering RNA (siRNA); can be referred to as small-noncoding RNA.

Nucleic acid footprinting A method of identifying regions of DNA which are exposed, not bound to protein, or not available because of conformation. This process can involve chemical modification or availability of the DNA to enzymatic cleavage.

Nucleobase An aromatic heterocyclic compound, a purine or pyrimidine, that is responsible for specificity of recognition.

Nucleoside The compound, a glycoside, formed by a covalent bond from a nucleobase to a ribose or deoxyribose ring at the C₁ position. Nucleoside analogues are useful drugs.

Nucleotide A nucleoside with a covalently bound phosphate group which is the monomer unit in nucleic acids. Nucleotide structures are also found in coenzymes such as nicotinamide adenine dinucleotide (NAD).

Polony A 'colony' of DNA molecules obtained by the replication of a single DNA template under conditions where the PCR product remains physically close to the DNA template.

Polymerase chain reaction A method by which a single strand of DNA is amplified to provide a large, homogeneous DNA sample. The method use a repetitive temperature cycle using a thermostable DNA polymerase to extend primer which binds to a known DNA sequence flanking the region of interest. Twenty cycles has the potential to provide 2²⁰ amplification. The polymerase chain reaction has a variety of applications including the preparation of samples for DNA sequence analysis.

Primer A short DNA or RNA oligonucleotide sequence with a free 3'-hydroxyl group that binds to a region on the DNA and serves as the nidus to start copy of a complementary strand.

Primer extension A technique used to detect modifications in RNA polymer. Primer extension is based on the reverse transcriptase extension of a synthetic DNA oligonucleotide complementary to the target RNA. Extension of the cDNA is compromised by the presence of a cleavage in the target RNA or a modified nucleobase.

Short reads Base sequence data of 25–100 bases which is most frequently obtained with second-generation sequencers.

Reverse transcriptase An enzyme which catalyzes the formation of a DNA strand from an RNA template.

RNAseq The use of next-generation DNA sequence technology to determine RNA structure.

Tautomerism A form of isomerization where the two forms are directly interconvertible as in the case of enol–keto isomerization. This differs from isomers such as propyl and isopropyl which are not interconvertible.

Template A single-stranded DNA or RNA, usually with a primer region attached, which serves to direct the sequence of synthesis of a complementary polynucleotide.

Introduction

The term nucleic acid was used to by R. Altmann in 1889 (cited in [Esanu, 1988](#)) to describe material obtained from salmon sperm and calf thymus. Clear recognition that there are two types of nucleic acids dates to the work of P.A. Levine and others more than 90 years ago ([Levine and London, 1929](#)). This work demonstrated that sugar content of thymonucleic acid was deoxyribose (deoxypentose) with adenine, guanine, cytosine, and thymine as the nucleobase components ([Figure 1](#)). Hammarsten ([Hammarsten, 1894](#)) had previously defined ribonucleic acid as containing pentose (ribose) with adenine, guanine, cytosine, and uracil as nucleobase

components ([Figure 1](#)). It has been subsequently shown that 5-methyl cytosine is present at a level of 1% ([Tost, 2009](#)) reflecting its importance in the regulation of gene expression ([Kulis and Esteller, 2010](#)).

As an indication of its large size, genomic DNA is expressed in weight (pg) and the size of the human genome (7 pg) is estimated to be 3.1 gigabases (3.1×10^9 bases) ([Doležal and Greilhuber, 2010](#)). Messenger RNA is smaller and is composed of a noncoding leader sequence (a 5'-UTR), a region coding for the primary structure of the protein and a 3'-UTR ([Mortimer et al., 2014](#)). Long-noncoding RNA are longer than 200 base pairs (bp) and structurally similar to messenger RNA ([Yan and Wang, 2012](#)). There are small RNA species which have been the

Figure 1 The structure of the common bases found in nucleic acids. Also shown is ribose (RNA) and deoxyribose (DNA). The ring numbering system for purine bases, pyrimidine bases, and the ribose moiety is shown.

subject of study in the past two decades (Cech and Steitz, 2014). Both DNA and RNA are polyanions reflecting the presence of a phosphoryl group. The negative charge on DNA is part of the basis for interaction with basic proteins such as histones although other factors are involved (Hadnagy *et al.*, 2008).

The function of nucleic acids is based on the complementary interaction of bases via hydrogen bonding as established by the Watson–Crick Model for DNA (Watson and Crick, 1953). Nucleobase are electron-rich heterocyclic aromatics which may contain exocyclic functional groups such as amino groups and hydroxyl groups which can exist in tautomeric forms (Figure 2). As a point of historical interest, it was when work on base-pairing with the enol forms was discarded in favor of the keto forms that it was possible for Watson to visualize the structure (Watson, 1968). Tautomerization can cause mistakes in base-pairing creating mutations (Goodman, 1995).

Nucleobases are joined to either ribose (RNA) or deoxyribose to form nucleosides (Figure 1). Nucleosides are converted to nucleotides by phosphorylation of the 5'-hydroxyl group. Nucleotide triphosphates are the substrates for the formation of DNA and RNA with the release of pyrophosphate and the formation of a phosphodiester bond through the 3' hydroxyl group on one ribose/deoxyribose and the 5' hydroxyl group on the adjacent ribose/deoxyribose ring. The development of nucleoside analogues has resulted in useful therapeutics for a variety of diseases including cancer, hepatitis B, and HIV (Figure 3). Nucleoside analogous can be cytotoxic, antiviral, or immunosuppressive in their action by several different mechanisms including direct enzyme inhibition, incorporation into either DNA or RNA resulting in loss of function, or inhibition of DNA synthesis.

Physical Structure of Nucleic Acid

The solution structure of nucleic acids is dominated by interaction with the various nucleobases. The double-helix of DNA is of great cultural fame (Watson, 1968) and of great biological importance. The genome is composed of double-stranded DNA which is held together by hydrogen bond and stacking of the nucleobases. The strands of DNA can be dissociated by denaturation (heat or base). The resulting single-stranded material obtained by heat denaturation will reform the original double-helical configuration if allowed to slowly cool; rapid cooling results in the formation of single-stranded random coils. The process of DNA denaturation/strand separation by heating is referred to as melting and is associated with an increase in UV absorbance at 260 nm. This increase in absorbance results from the 'destacking' of the nucleobases in the DNA. A plot of absorbance at 260 nm versus temperature, the DNA melting curve, is usually sigmoidal and the midpoint is designated T_m and is considered an attribute of the particular nucleic acid species (Figure 4). Fluorophores can bind to DNA and insert into the helical region in a process called intercalation; this binding is associated with an increase in fluorescence which is lost on strand separation (Figure 4). The T_m and the shape of the melting curve are related to DNA composition and the T_m increases with increasing GC content. Single-stranded DNA can renature with other DNA molecules in a process called hybridization. Hybridization can be used to measure the complementarity of single DNA molecules with the sensitivity of detecting single nucleotides polymorphisms (Lipsky *et al.*, 2001).

There are higher-order DNA complexes with triplexes (Fox and Brown, 2011) and quadriplexes (Tarsounas and Tijsterman, 2013). DNA molecules with catalytic activity,

Figure 2 Tautomerization of nucleobases.

Figure 3 Nucleoside analogues as drugs.

deoxyribozymes, have been described (Faulhammer and Famulok, 1997). DNA aptamers are short, synthetic DNA molecules that bind to specific targets; aptamers are obtained by Systematic Evolution of Ligands by Exponential Enrichment (SELEX) techniques (Marimuthu *et al.*, 2012). DNA aptamers can be single-stranded or more complex such as G-quadruplex DNA aptamers (Tucker *et al.*, 2012).

RNA exists in a variety of forms including messenger RNA, transfer RNA (t-RNA) which carries amino acids to be incorporated in the growing polypeptide chain on ribosomes, and microRNA which are involved in the regulation of transcription. MicroRNA species are also used to 'knock down' gene expression (Cullen, 2006) and may well have therapeutic utility (Akagi *et al.*, 2014). The microRNA species are known as small interfering RNA (siRNA). These are relatively small, double-stranded RNA which binds to the target mRNA initiating degradation of the mRNA resulting in the termination of translation (Snead and Rossi, 2012).

Chemical Modification of Nucleic Acids

Early use of chemical modification formed the basis for the histochemical identification of nucleic acid components in tissues and the Feulgen reaction continues to be used for the histochemical analysis of DNA (Fleskens *et al.*, 2010). The Feulgen reaction is based on the acid-catalyzed removal of purine bases from the deoxyribose resulting in the formation of an aldehyde which can be detected with Schiff's reagent. The chemical modification of nucleic acids is not as complex as that of proteins since there are fewer monomer units and less

diversity of nucleophilic reactive group. Reaction at the primary amine groups of adenine is referred to as exocyclic modification, whereas reaction at the imine nitrogens or at carbon atoms in pyrimidine or purine rings is referred to as an endocyclic modification. There are also ring-opening reactions and cross-linking reactions involving the nucleic acid bases. Other than cleavage of the glycosidic bond, reaction at the ribose ring does not usually occur. Mortimer and Weeks (2007) did show that reaction at the 2'-hydroxyl group could occur (Figure 5) and used this modification to study RNA conformation by SHAPE (selective 2'-hydroxyl acylation analyzed by primer extension) chemistry.

Modification of nucleic acid with dimethyl sulfate (DMS) (Figure 5) was important for early DNA sequencing methods (Maxam and Gilbert, 1977). *N*-Methyl *N'*-nitro-*N*-nitrosoguanidine, DMS, and methyl methanesulfonate (Figure 5) are used to modify DNA for the study of DNA repair mechanisms (Wyatt and Pittman, 2006).

Diethylpyrocarbonate (Figure 6) reacts with adenine and guanine bases in nucleic acids resulting in rupture of the purine ring and subsequent cleavage of the glycosidic bond. Diethylpyrocarbonate was introduced into nucleic acid purification protocols as a general nuclease inhibitor. The finding that there was a reaction between nucleic acid and diethylpyrocarbonate prompted an investigation of the mechanism(s) of a possible reaction (Solymosy *et al.*, 1971). The conformational sensitivity of the reaction of diethylpyrocarbonate with nucleic acids is useful in determining DNA distortions (Kahl and Paule, 2009). Kethoxal (3-ethoxy-1,1-dihydroxy-3-butanone) (Figure 6) is specific for the modification of guanine bases in RNA (Litt, 1971) and is used for the study of the conformation of RNA in

Figure 4 DNA melting curve.

macromolecular complexes (Kostopoulou *et al.*, 2013). Mortimer *et al.* (2009) suggest that reaction with (*N,N*-dimethylamino) dimethylchlorosilane (Figure 6) is a more accurate measure of the accessibility of guanine. Environmentally significant aldehydes such as acrolein and the closely related crotonaldehyde, acetaldehyde, and 4-hydroxy-2-nonenal react with nucleic acids. The products of the reaction of exogenous aldehydes with DNA are referred to as DNA adducts (Minko *et al.*, 2009). Permanganate oxidation has also been used to study DNA mutation by detection of mismatches in DNA (Kahl and Paule, 2009). The key to these various applications is the reaction of permanganate with an unpaired or mismatched thymine; in other words, the fully complementary site is resistant under mild reaction condition while the exposed or reactive site is highly susceptible to oxidation. Tabone *et al.* (2006) used the absorbance of the hypomanganese diester to develop a microplate assay for mutation scanning based on mismatching in base-pairing.

DNA Modification by Radiation

DNA is subject to modification by radiation. This damage included chemical modification of nucleobases and DNA strand cross-linking resulting from the absorption of light by the various nucleobases. Ionizing radiation can damage DNA by multiple mechanisms including the generation of free radicals from the ionization of water resulting in DNA strand cleavage (Peak and Peak, 1990). The production of hydroxyl radicals from water is also used for DNA footprinting (Franchet-Beuzit *et al.*, 1993). Unlike UV radiation, ionizing radiation can cause DNA damage at the sugar ring (von Sonntag, 2014). Irradiation of nucleic acids with UV light (254 nm) results in the hydration of pyrimidine rings. There is interest in the use of natural antioxidants in protecting against radiation, visible and UV, damage (Malhomme de la Roche *et al.*, 2010).

Figure 5 Chemical modification of nucleobases and nucleosides.

DNA Mapping

5-Methylcytosine (Adams, 1995) and its hydroxymethyl derivative (Pfeifer and Szabo, 2009; Figure 7) may be the best known epigenetic modification. Sodium bisulfite converts cytosine to uracil in a deamination reaction while the deamination reaction with 5-methylcytosine is two orders of magnitude slower permitting the identification of cytosine methylation sites in DNA. Sodium bisulfite does not distinguish between 5-methylcytosine and 5-hydroxymethylcytosine (Jin *et al.*, 2010) and other approaches are required (Nestor *et al.*, 2014). DMS is used for DNA mapping studies where there is preferential modification of guanine. DNA is susceptible to alkali-induced cleavage at methylated purine residues which permits use for genomic footprinting of DNA (Toth *et al.*, 1990). DMS is also used for footprinting of RNA where modification at adenine and cytidine can be determined by reverse transcriptase (RT) (primer extension) (Tijerina *et al.*, 2007). Footprinting with DNaseI or hydroxyl radical is used to map sites of protein interaction with DNA (Hampshire *et al.*, 2007).

Nucleic Acid Sequencing

Modern personalized medicine is built on our ability to determine the sequence of bases in a patient's DNA. Variants in

DNA sequence from the population 'normal' are at the root of many inherited and acquired disease processes. The diagnosis of inherited diseases by DNA sequencing is now considered a routine clinical practice. Our ability to interrogate a patient's genetic makeup has evolved over the past three decades from the sequencing of individual regions of selected genes to the routine sequencing of all protein coding regions in a patient's entire genome (Miller *et al.*, 2014). The use of DNA sequencing techniques, however, is not restricted to inherited disease diagnosis. DNA sequencing is used to understand how a patient may respond to a specific drug, what dose of a drug is most appropriate, or what side effects could be expected. Collectively, this is the field of pharmacogenomics. DNA sequencing is also routinely used in the context of cancer to find mutations in key tumor suppressor genes or oncogenes. These data are used not only to subtype or diagnose different neoplastic diseases, but also to develop patient specific prognoses. Finally, chemotherapeutics have been developed which target oncogenes (primarily tyrosine kinases) with specific activating DNA mutations. Sequencing of a tumor's DNA to detect these mutations to help guide therapy is now the standard of care. All of these advances stem from two key innovations: (1) development of the dideoxy method for DNA sequencing, referred to as Sanger sequencing and (2)

Figure 6 Diethylpyrocarbonate and Kethoxal modification of nucleobases.

development of massively parallel DNA sequencing through synthesis, a group of techniques collectively known as 'next-generation' sequencing (NGS). The current techniques used for DNA sequencing (both Sanger and NGS) exploit the machinery that exists in nature for DNA replication, specifically, DNA polymerases.

Sanger DNA Sequencing

Fred Sanger had already been awarded a Nobel Prize for work on the determination of protein sequence when he developed what is known as the dideoxy method or Sanger sequencing (Sanger *et al.*, 1977). This method is based on the ability of modified dideoxynucleotide (e.g., dideoxyadenine; Figure 8) to terminate DNA extension by a DNA polymerase.

The first step in Sanger sequencing is the selection of the DNA region to be sequenced. This could be a specific coding exon in the gene that causes cystic fibrosis (CFTR). This could be a DNA sequence within a bacterium that causes antibiotic resistance. The options are only limited to things with nucleic acids. In case of large DNA, the DNA fragment is broken into smaller pieces which are assembled into plasmids flanked by

known DNA sequences. Polymerase chain reaction (PCR) primers are designed to target the region to be sequenced. These PCR primers are short oligonucleotides (20–30 bp) and are the complement to DNA sequences that flank the 5' and 3' sides of the target DNA. Typically, PCR primers are designed to amplify several hundred base pairs in the target DNA sequence. PCR amplification is then performed to provide sufficient homogeneous sample for sequence analysis. Excess PCR primers and deoxynucleotides are removed. Sanger sequencing of the purified PCR amplification product is then performed. The Sanger method begins with a third oligonucleotide primer that is designed to be the complement to one end of the DNA region to be sequenced. This primer is referred to as the 'sequencing primer.' Like the PCR primers, the sequencing primer is a short synthetic oligonucleotide (20 or so base pairs long). This primer is added to the PCR amplification product, along with a heat stable polymerase, deoxynucleotides (dATP, dCTP, dGTP, dTTP) and a lower concentration of fluorescently labeled 3' dideoxynucleotides (ddATP, ddCTP, ddGTP, ddTTP). Each dideoxynucleotide is labeled with one of four different fluorophores. The mixture is heated and cooled to allow the sequencing primer to anneal to its target sequence. The polymerase then incorporates deoxynucleotides using the PCR

Figure 7 Reaction of methylcytosine with sodium bisulfite.

amplification product as a template until a dideoxynucleotide is incorporated. Without a 3' OH on the ribose group, further extension is not possible. The result is multiple DNA oligonucleotides, each ending with a dideoxynucleotide, which are the complement to the target sequence. Each of these resulting products is fluorescently labeled with one of four fluorophores, depending on which dideoxynucleotides terminated the growth of the nascent DNA chain. Using fluorescent capillary electrophoresis, the sequence of the original DNA can be inferred (**Figure 8**; Huang *et al.*, 1992).

NGS

NGS can be broadly defined as any DNA sequencing technology beyond Sanger sequencing. An excellent review of NGS sequencing methods is available (Metzker, 2010). NGS approaches have many similarities with Sanger sequencing. Both exploit the natural DNA replication machinery to derive DNA sequence (e.g., a DNA polymerase using a 'sequencing' primer and target sequence as a template). In addition, PCR amplification plays an important role in the preparation of the DNA target regions to be sequenced in both approaches. Two features are unique to NGS approaches: (1) they are applied to single DNA molecules, while Sanger sequencing looks at all DNA molecules in a 'sequencing reaction' in aggregate; (2) they generate real-time sequence data as each new nucleotide is incorporated into a nascent DNA strand. The steps involved in NGS can be broadly grouped into

Sanger sequencing

	5' → 3'

								Primer

Figure 8 Sanger or dideoxy sequencing.

three main parts: (1) library preparation, (2) sequencing through DNA synthesis, and (3) data analysis.

Library Preparation

As with Sanger sequencing, the first step in NGS is the selection and amplification of the target DNA regions to be

sequenced. In Sanger sequencing, a defined region of less than 500–600 bases is selected. In next-generation approaches, there is no limit to the size or complexity of the target DNA regions. One could select a single exon of a single gene to PCR amplification and purification, as in the Sanger sequencing (example above). Alternatively one could develop a multiplex PCR approach and amplify all exons for a particular gene, or all exons for multiple genes. Instead of selecting regions by PCR, one could employ a physical capture method. In these approaches, short oligonucleotide sequences are physically immobilized onto a solid support surface. These oligonucleotides are the complement to the target sequences to be ‘captured.’ Extracted DNA is physically sheared or enzymatically cleaved and added to these immobilized capture probes. Unbound DNA is eluted and what remains is the target DNA of interest. Using these approaches, one could capture many genes at once, or even all coding sequences within the human genome. Finally, one could simply start with the entire human genome as the target sequence. The selected, amplified, captured, or targeted DNA sequences are either enzymatically digested or physically sheared to multiple diverse sequences of one to two hundred base pairs in length. Alternatively, using PCR-based selection approaches, amplicons are intentionally designed to be small (100–200 bp). These small fragments of DNA are end-ligated to an ‘adapter’ of defined/known sequence. This adapter is a small oligonucleotide that will be used to capture individual pieces of DNA and also used as a known sequence for further PCR amplification. At this point, library creation is complete (Head *et al.*, 2014).

Sequencing through DNA Synthesis

The next step in the sequencing process is the physical separation and PCR amplification of individual DNA molecules in the DNA fragment library prepared above. This is done through the use of the ligated adapters. There are two main methods for physical separation and amplification. The first uses very small beads which are coated with the complement oligonucleotide to the ligated adapter sequence. Beads and denatured library DNA are mixed in a defined ratio to ideally achieve a single DNA molecule hybridized to each bead. Excess DNA is washed away and the beads are added to an oil-aqueous emulsion in such a way as to have a single bead in each aqueous bubble. Also contained in this mixture are a heat stable polymerase, dNTPs, and primers that hybridize to the library adapter sequence. Each aqueous bubble can be thought of as an individual PCR reaction chamber. During PCR, copies are made of the individual sequence. These are contained within the aqueous bubble and re-hybridize to the target bead. After PCR is performed, each bead contains many identical copies of the individual DNA molecule that was originally hybridized to the bead. The second approach uses a single solid support coated with the complement to the ligated library DNA adapter. Library DNA is denatured and hybridized to this solid support. An amplification reaction is then performed. When new DNA molecules are synthesized from their captured template they hybridize back onto the solid support adjacent to their parent. Through multiple iteration of

amplification, tiny islands of DNA, all derived from the same sequence, are created.

The next step in this process is sequencing of the DNA bound to each individual bead or from each isolated DNA island (Figure 9). Pyrosequencing is ideally suited to the bead-based approaches (Harrington *et al.*, 2013). The beads are loaded into a honeycomb-welled plate. Each well is loaded to contain an individual bead; each bead is coated with a unique clonal DNA sequence. A deoxynucleotide (e.g., dATP), ADP, sulfurylase, luciferin, firefly luciferase, and a DNA polymerase are added to the plate. If the nucleotide (e.g., dATP) is incorporated by the DNA polymerase into the sequence attached to the bead, pyrophosphate is released. Pyrophosphate is converted to ATP by sulfurylase using ADP as a substrate. Luciferase then takes the substrates luciferin and ATP to produce light. In short, if the deoxynucleotide is incorporated into the DNA attached to a bead, the well containing that bead will glow. From this, it can be inferred that the sequence starts with the complement to the nucleotide added (i.e., if dATP was added, the sequence starts with a T). Next dCTP is added using the same approach, with the same result; a glowing well indicates that the next nucleotide in the target sequence is a G. Next comes dGTP and then dTTP. This cycle is repeated hundreds of times. Each time, a glowing well indicates the incorporation of the added nucleotide. Raw data are literally the amount of light produced by each well in each cycle. From this, the sequence of each bead-attached clonal DNA population can be inferred. In a single plate, millions of individual beads can be sequenced, resulting in hundreds of millions of sequenced nucleotides from the short 100–200 bp fragment sequence library. The analysis of millions of individual ‘reactors’ is why this approach is often referred to as ‘massively parallel’ DNA sequencing. Newer bead-based sequencing approaches can detect a change in pH in each reactor well that occurs with the incorporation of a nucleotide and associated release of pyrophosphate. This simplifies the chemistry behind the sequencing process.

For the solid support approach, modified dNTPs are used in the sequencing reaction. These modifications include a 3’ OH blocking group and a fluorophore. The cycle of sequencing is conceptually very similar to the bead-based approach. To the solid support, a DNA polymerase and a single modified dNTP (e.g., dATP) is added. If the dATP is incorporated the tiny DNA island will fluoresce. A picture is taken and the blocking agent and fluorophore are chemically removed. Each dNTP is added in turn (ddAPT, ddCTP, ddGTP, ddTTP) and the process is cycled hundreds of times. The end result is an inferred sequence based on the fluorescence, or lack thereof, in each cycle for each clonal DNA island. As with the bead-based approach, this can produce millions of individual 100–200 bp long sequence reads, one for each DNA island.

Data Analysis

The end result of the wet work above is hundreds of thousands to millions of individual short DNA ‘reads.’ If a single DNA amplicon was sequenced, all of the millions of reads would be of this one short sequence. The number of times that an individual sequence is seen as a DNA island or on a DNA-coated bead is referred to as the ‘read depth.’ A read depth of one

Second-generation sequencing technologies

Reversible chain termination

Real time sequencing

Figure 9 Methods for measuring DNA sequence analysis by synthesis.

million for a single DNA sequence in almost every situation would be excessive. If the entire coding sequence from a human genome was used to create the library, each individual read could be from any of the originally captured exons. This would lead to a smaller read depth for any one sequence but a much broader coverage across multiple individual DNA regions.

There are two challenges in the analysis of NGS data: the alignment of these individual short reads to the target genome (Schbath *et al.*, 2012) and the identification and annotation of base pair changes from the reference sequence (Nielsen *et al.*, 2011). Sequence alignment is computationally intense. When sequencing from the entire human genome, the target reference sequence is approximately 3 billion bases. To find where a single 100–200 bp fragment best fits within this reference sequence, particularly when the match might not be exact, takes special annotation of the target genome and alignment algorithms that are well beyond the scope of this article. Suffice it to say that aligning sequence from even a subset of the

human genome (e.g., all coding sequences, also referred to as the 'exome') takes many, many hours on even the fastest multiprocessor servers. The next step is a bit more straightforward; if a change from the reference sequence is found, it must be annotated as (1) a normal sequence variant of no clinical significance, (2) a disease causing or disease associated sequence variant, or (3) a variant of unknown clinical significance. While this can be a time-consuming process for the scientist or physician, databases exist which annotate all currently known sequence variants in the human genome. These are, by no means, complete, but are commonly used as a 'first pass' for sequence annotation (Nielsen *et al.*, 2011).

Future Directions

These NGS approaches have moved from the research laboratory to the clinic. Many laboratories routinely use NGS to

perform testing on patients. The great majority of these tests are developed by individual clinical labs. However, the Food and Drug Administration (FDA) has recently approved its first NGS platform for the full sequencing of the cystic fibrosis transmembrane conductance regulator (CFTR) gene for the diagnosis of CF in symptomatic patients.

The field of DNA sequencing continues to evolve and develop. On the analysis side, we can determine much more than sequence variants. Newer analysis algorithms allow for the determination of DNA copy number. This is very useful in detecting gene deletions and duplications. It has also been used on the research side to quantitate the expression of RNA transcripts, referred to as 'RNAseq' (Fox-Walsh *et al.*, 2011). Newer instrument methods for DNA sequencing focus on longer reads, faster data acquisition, and reduced costs with the goal of facile and economical acquisition of genomic sequence for the purpose of personalized medicine (Miller *et al.*, 2014). The majority of these technologies are still in the development phase. One approach is based on the 'real-time' analysis of the sequencing of a single DNA molecule in real time (Bashir *et al.*, 2012). This technique uses a unique device (zero-mode waveguide, ZMW) to measure the incorporation of a single individual deoxyribonucleotide triphosphates into a single DNA molecule. This approach has the advantage of 1000 base reads (English *et al.*, 2012). One other new approach that has received much notice is nanopore sequencing. Nanopore sequencing is based on the measurement of ion current levels as a DNA molecule is moved through a protein nanopore (Lazlo *et al.*, 2014). A portable device for nanopore sequencing has been developed (Quick *et al.*, 2014) raising the possibility of point of care NGS. While this still feels like a far off dream, 20 years ago, the idea that we could sequence the entire human genome if a few days for a few thousand dollars would have sounded crazy.

The Chemical Synthesis of DNA and RNA Oligonucleotides for Drug Development and Synthetic Biology Applications

SL Beaucage and HV Jain, US Food and Drug Administration, Silver Spring, MD, USA

© 2016 Elsevier Inc. All rights reserved.

Introduction

The ability to design and synthesize DNA and RNA sequences has had a massive impact on biotechnology particularly in the rapidly growing fields of synthetic biology and nucleic acid-based drug development. Indeed, the chemical synthesis of DNA primers for amplification of specific DNA sequences via the polymerase chain reaction or DNA probes for the detection of RNA and DNA through Watson–Crick base-pairing recognition, has revolutionized modern molecular biology. The use of synthetic DNA/RNA sequences and their analogs for recognition and binding to messenger RNAs encoding disease-causing proteins has led to the production of nucleic acid-based drugs capable of inhibiting the expression of these proteins through either an antisense or an RNA interference pathway for therapeutic applications (Crooke, 2004). Furthermore, the ability to construct entire genes through enzymatic assembly of synthetic DNA sequences has enabled the total synthesis of *Mycoplasma genitalium* mouse mitochondrial genomes and the genome of an entire microorganism (Gibson *et al.*, 2010), thereby underscoring the power of chemically synthesized DNA in the realm of synthetic biology, genomics, and gene therapy. In this context, the *in situ* synthesis of DNA sequences on microarrays has also become a versatile tool for widespread applications including biomarker detection, high-throughput genomics, drug discovery, and synthetic biology. Moreover, *in situ* synthesized oligonucleotide arrays can also

be used to generate pools of mixed DNA sequences for potential use in gene assembly (Tian *et al.*, 2004).

The chemical synthesis of DNA and RNA sequences has a long history; several DNA and RNA synthetic approaches based on the phosphate diester (Khorana *et al.*, 1972) and phosphate triester methods (Itakura *et al.*, 1984) have been reported for this purpose. Although these methods had significantly contributed to unraveling important biological problems, they are now of historical interest and will not be discussed in this article. More recent methodologies that are amenable to automated DNA/RNA synthesis on solid supports and on microarrays will be the focus of this report.

The Chemical Synthesis of Oligodeoxyribonucleotides

The Phosphoramidite Approach

The development of deoxyribonucleoside phosphoramidites is derived from the pioneering work of Letsinger and his coworkers on the use of deoxyribonucleoside chlorophosphites as synthetic intermediates (Letsinger and Lunsford, 1976). As shown in Scheme 1, the reaction of 5'-O-protected thymidine (1) with the bifunctional phosphitylating reagent 2 provides the deoxyribonucleoside chlorophosphite 3, within 5 min at -78°C , along with the symmetrical (3'→3')-dinucleoside phosphite triester 4. Addition of 3'-O-protected thymidine

Scheme 1 The phosphite triester approach to the synthesis of DNA sequences. R, phenoxyacetyl; Thy, thymine-1-yl; MMTr, 4-methoxytrityl.

Scheme 2 Replacement of deoxyribonucleoside chlorophosphites (**7**) with deoxyribonucleoside phosphoramidites (**8**) for the synthesis of DNA sequences. DMTr, 4,4'-dimethoxytrityl; B^P, protected pyrimidine and purine nucleobases; Lev, levulinyl.

followed by aqueous iodine oxidation results in the formation of dinucleoside phosphate triesters (**5** and **6**) within 1 h.

The formation of internucleoside linkages with such kinetics had been unprecedented in the mid-1970s. Because of the high reactivity and sensitivity of deoxyribonucleoside chlorophosphites to air oxidation and hydrolysis, these compounds had to be prepared immediately prior to use and stored under an inert atmosphere at -78°C . Furthermore, the production of variable amounts of **4** has made it difficult to consistently maintain the stoichiometry of **3** for optimal coupling efficiency. These limitations have compromised the automation of deoxyribonucleoside chlorophosphites for the synthesis of DNA sequences. Replacement of the chlorine atom of deoxyribonucleoside chlorophosphites **7** with a dimethylamino function has led to deoxyribonucleoside phosphoramidites **8** (Scheme 2), which have been introduced in the early 1980s as a novel class of reagents for the synthesis of DNA sequences (Beaucage and Caruthers, 1981).

The synthesis of these reagents consists of reacting suitably protected deoxyribonucleosides with chloro-(*N,N*-dimethylamino)methoxyphosphine in the presence of *N,N*-diisopropylethylamine. The phosphoramidites **8** are isolated as powders, stable to air oxidation and hydrolysis under normal laboratory conditions. The ability to convert these relatively stable phosphoramidites to highly reactive intermediates, under weakly acidic conditions, is the hallmark of the phosphoramidite approach to the synthesis of oligodeoxyribonucleotides. Typically, the reaction of **8** with 3'-*O*-levulinyl deoxythymidine in the presence of 1*H*-tetrazole produces, within minutes, the dinucleoside phosphite triesters **9**, which are ultimately oxidized to the phosphate triesters **10** (Scheme 2) in near quantitative yields based on ³¹P nuclear magnetic resonance (³¹P NMR) spectroscopy evidence (Beaucage and Caruthers, 1981). The phosphoramidite strategy has been successfully applied to the synthesis of various DNA sequences (Caruthers *et al.*, 1982) through the use of properly functionalized silica gel-based solid support (Köster, 1972; Matteucci and Caruthers, 1981). Over the years, the phosphoramidites **8** have been subjected to minor structural modifications in order to improve the stability of phosphoramidite monomers to the conditions used for solid-phase

Figure 1 Structural modifications of the original deoxyribonucleoside phosphoramidite monomers (**8**) leading to their modern commercial versions (**11**). DMTr, 4,4'-dimethoxytrityl; B^P, protected pyrimidine and purine nucleobases.

DNA synthesis. These modifications include the replacement of the original dimethylamino function with other *N,N*-dialkylamino or *N,N*-cycloalkylamino groups and replacement of the methoxy P(III) protection with a variety of functionalized alkoxy groups (Beaucage and Iyer, 1992; Iyer and Beaucage, 1999) often at the expense of phosphoramidite reactivity. Out of all those proposed phosphoramidite modifications, the most popular deoxyribonucleoside phosphoramidites that have been used since the mid-1980s are the phosphoramidites **11** (Figure 1; Sinha *et al.*, 1984).

As shown in Scheme 3, the solid-phase synthesis protocol consists of: (1) cleaving the 5'-protecting group of a deoxyribonucleoside covalently attached to controlled-pore glass (CPG, **12**) under acidic conditions; (2) performing the reaction of **11** with the 5'-hydroxy function of **13** in the presence of 1*H*-tetrazole to produce the dinucleoside phosphite triester **14** along with some unreacted **13**; (3) capping the 5'-hydroxyl of unreacted **13** by acylating reagents to prevent further chain extension of this impurity; and (4) converting the phosphite triester **14** to its phosphate triester **15** using an appropriate oxidant. The synthesis protocol is then iteratively repeated until the desired chain length is obtained; the DNA sequence is finally exposed to aqueous or gaseous alkylamines to remove the amino protecting groups of the nucleobases while concomitantly cleaving the phosphate protecting groups and releasing the 5'-protected DNA sequence from the solid support.

Scheme 3 The phosphoramidite approach to the solid-phase synthesis of DNA or RNA sequences. DMTr, 4,4'-dimethoxytrityl; CPG, controlled-pore glass; R¹, protecting group; B^P, protected pyrimidine and purine nucleobases; B, thymine-1-yl/uracil-1-yl, cytosine-1-yl, adenine-9-yl, or guanine-9-yl.

Figure 2 Chemical structure of the 4,4'-dimethoxytrityl (**16**), 9-phenylxanthen-9-yl (**17a**), and 9-(*p*-tolyl)xanthen-9-yl (**17b**) groups for 5'-hydroxy protection.

Hydrophobic 5'-protecting groups are often left intact in order to facilitate the separation of the DNA sequence from shorter than full-length sequence impurities using reversed-phase high-performance liquid chromatography (RP-HPLC) techniques (Iyer and Beaucage, 1999). The hydrophobic 5'-protecting group is removed after RP-HPLC purification of the DNA sequence is done.

Over the years, attempts have been made to improve individual steps of the solid-phase synthesis protocol described in Scheme 3. It is important to adequately protect the exocyclic amino groups of cytosine, adenine, and guanine moieties to prevent 'branching' of the DNA sequence during the course of its assembly. The base-labile acetyl, benzoyl, and isobutyryl groups for amino-protection of cytosine, cytosine or adenine and guanine, respectively, have been routinely used for this purpose, whereas the phenoxyacetyl and dimethylformamide groups have been recommended for amino-protection of cytosine/adenine and guanine, respectively, when milder basic deprotection conditions are required for specific applications. These nucleobase protecting groups are currently the most popular ones among those that have been proposed over the past 50 years (Iyer and Beaucage, 1999).

The acidic conditions used for the iterative cleavage of the 5'-O-dimethoxytrityl (DMTr) protecting group (**16**, Figure 2) during solid-phase synthesis of DNA sequences have been reassessed; the use of 3% trichloroacetic acid or 1.5% dichloroacetic acid in dry dichloromethane over a period of 20 or 60 s, respectively, has been found optimal for this purpose (Tram et al., 2011). Although the 9-phenylxanthen-9-yl group (Px, **17a**) and its 9-(*p*-tolyl)xanthen-9-yl derivative (**17b**) (Reese and Yan, 2004) have been proposed as attractive alternative 5'-O-protecting groups (Figure 2), the DMTr group remains the most popular 5'-hydroxy protective group for solid-phase synthesis of DNA sequences.

The development of acidic activators for deoxyribonucleoside phosphoramidite monomers has been the focus of intense scrutiny. Although 1*H*-tetrazole is still the most widely used phosphoramidite activator for solid-phase DNA synthesis, the coupling efficiency of deoxyribonucleoside phosphotetrazolide intermediates (Bernier et al., 1989) decreases when used in the synthesis of sterically demanding DNA or RNA sequences. In this regard, more acidic activators than 1*H*-tetrazole ($pK_a=4.9$), namely, 5-(4-nitrophenyl)-1*H*-tetrazole ($pK_a=3.7$), 5-(bis-3,5-trifluoromethylphenyl)-1*H*-

tetrazole ($pK_a=3.4$), 5-benzylthio-1*H*-tetrazole ($pK_a=4.1$), and 5-ethylthio-1*H*-tetrazole ($pK_a=4.3$) have been found more potent in terms of coupling kinetics and efficiencies for both solid-phase DNA and RNA synthesis (Wei, 2013). However, it should be noted that premature cleavage of the 5'-DMTr group leading to phosphoramidite double-couplings and degradation of the tricoordinated phosphite triester linkages are known to occur with the use of increasingly acidic activators. Several other classes of nucleoside phosphoramidite activators have also been investigated over the years (Wei, 2013); those include other azoles, azolium, pyridinium, saccharin and ammonium salt complexes, carboxylic acids, Lewis acids, trimethylchlorosilane, and 2,4-dinitrophenol. Currently, 1*H*-tetrazole, 5-benzylthio-1*H*-tetrazole, 5-ethylthio-1*H*-tetrazole, and 4,5-dicyanoimidazole are widely employed in the solid-phase synthesis of native and modified DNA and RNA sequences.

Although activated deoxyribonucleoside phosphoramidite monomers lead to high coupling efficiencies, coupling yields are not quantitative. Any unreacted DNA sequences should be deactivated through an acylation reaction in order to prevent further extension of those 'failure' sequences, which can complicate the purification of the desired DNA sequence from shorter than full length ones. The acylation reaction has also been shown to be effective in reducing the extent of guanine phosphorylation at O-6 during the coupling step of the solid-phase synthesis cycle (Pon et al., 1986). It is also recommended to perform this acylation reaction prior to the oxidation step, which would otherwise convert O⁶-phosphitylated guanine residues into more hydrolytically stable O⁶-phosphorylated congeners and result in the formation of an unwanted sequence ramification site at each modified guanine. The acylation of unreacted DNA sequences, is still performed nowadays in routine solid-phase DNA synthesis protocols.

Oxidation of the phosphite triester **14** to phosphate **15** is the last step of the solid-phase DNA synthesis protocol (Scheme 3). An aqueous solution of iodine and 2,6-lutidine (Letsinger and Lunsford, 1976) or pyridine (Usman et al., 1985) is generally used for this purpose primarily because this formulation is stable and provides rapid-reaction kinetics, usually without formation of side products. However, for specific applications, nonaqueous oxidizing reagents may advantageously offer an alternative to aqueous iodine for the oxidation of oligodeoxyribonucleoside phosphite triesters. These reagents (Beaucage and Iyer, 1992; Uzagare et al., 2003) include *m*-chloroperbenzoic acid, iodobenzene diacetate and tetra-*n*-butylammonium periodate, *tert*-butyl hydroperoxide and various hydroperoxides, dimethyldioxirane and ethyl(methyl)dioxirane, (1*S*)-(+)-(10-camphorsulfonyl)oxaziridine, and *N*-bromosuccinimide-dimethyl sulfoxide (DMSO). Out of these oxidants, an aqueous solution of iodine in pyridine, *tert*-butyl hydroperoxide and (1*S*)-(+)-(10-camphorsulfonyl)oxaziridine are most commonly used in the solid-phase synthesis of native and modified DNA sequences. The oxidation of phosphite triester **14** is particularly important, when it relates to the chemical synthesis of DNA sequences with internucleotide phosphorothioate diesters, which by virtue of their enhanced resistance to hydrolysis catalyzed by nucleases (Eckstein, 1985), have been extensively

Figure 3 Potent sulfur-transfer reagents for converting internucleotidic phosphite triesters to phosphorothioate triester functions.

used as antisense sequences in the inhibition of gene expression. Automated synthesis of these modified oligonucleotides via the phosphoramidite method consists of replacing the aqueous iodine oxidation step with a sulfurization reaction that has originally been effected by elemental sulfur (Stec and Zon, 1984). The poor solubility of elemental sulfur in organic solvents has made its use, in automated systems, difficult. This problem has been resolved when phenylacetyl disulfide (Kamer *et al.*, 1989) and 3H-1,2-benzodithiol-3-one 1,1-dioxide (Iyer *et al.*, 1990) have been employed as sulfurization reagents. The success of these sulfur-transfer reagents in the automated synthesis of phosphorothioate DNA sequences has prompted the development of additional sulfurizing reagents. These sulfur-transfer agents (Beaucage and Caruthers, 2000) include *N,N,N',N'*-tetraethylthiuram disulfide, dibenzoyl tetrasulfide, bis-(*O,O*-diisopropoxyphosphinothioyl) disulfide, benzyltriethylammonium tetrathiomolybdate, bis-(*p*-toluenesulfonyl)disulfide, 3-ethoxy-1,2,4-dithiazoline-5-one, thiiranes, bis(ethoxythiocarbonyl)tetrasulfide, 3-methyl-1,2,4-dithiazoline-5-one, and 5-(dimethylaminomethylidene)amino-3H-1,2,4-dithiazole-3-thione (Guzaev, 2011). Out of those sulfur-transfer reagents, 3H-1,2-benzodithiol-3-one (18), phenylacetyl disulfide (19), and 5-(dimethylaminomethylidene)amino-3H-1,2,4-dithiazole-3-thione (20) are currently the most extensively used in solid-phase synthesis of oligonucleoside phosphorothioates (Figure 3).

An alternate two-step version of the phosphoramidite synthesis cycle has been reported to provide a simpler and more robust automation with significant cost reduction, when undertaking the large-scale synthesis of DNA sequences (Sierzchala *et al.*, 2003). The highpoints of this method are replacement of the 5'-DMTr blocking group with an aryloxycarbonyl protective group and the use of DMTr protection for the exocyclic amino functions of adenine and cytosine. A peroxy anion serves as a nucleophile to iteratively and simultaneously remove the 5'-O-carbonate protecting group and oxidize phosphite triesters to their tetracoordinated phosphate triester counterparts. However, for some reasons, this two-step synthesis cycle for the solid-phase synthesis of DNA sequences has not so far gained popularity among end users.

The *H*-Phosphonate Approach

H-Phosphonate monoesters are a distinct class of tetra-coordinated phosphorus compounds, which upon activation, are amenable to reaction with nucleophiles, thereby making them attractive for the preparation of oligonucleotides. The formation of *H*-phosphonate diesters from the reaction of *H*-phosphonate monoesters with diphenyl phosphorochloridate and a protected nucleoside had first been

demonstrated in the 1950s (Hall *et al.*, 1957). However, the use of *H*-phosphonate monoesters in the synthesis of oligonucleotides has been reevaluated in the mid-1980s. Deoxyribonucleoside *H*-phosphonates (21, Scheme 4) are key intermediates in the solid-phase synthesis of DNA sequences; these compounds are currently commercially available or can easily be prepared (Stawinski and Strömberg, 2001).

The solid-phase synthesis of DNA sequences via *H*-phosphonates consists of cleaving the 5'-DMTr group of a deoxyribonucleoside covalently attached to CPG (12) under acidic conditions and performing the reaction of 13 with 21 in the presence of pivaloyl chloride to produce the dinucleoside *H*-phosphonate diester 22. As shown in Scheme 4, the synthesis protocol can iteratively be repeated until the desired chain length is obtained; the DNA sequence is then subjected to an aqueous iodine treatment in the presence of pyridine or *N*-methylmorpholine to convert all phosphonate diester functions to native phosphate diesters. Given the sensitivity of *H*-phosphonate diesters to mildly alkaline conditions, a second aqueous iodine treatment in the presence of triethylamine is necessary to accelerate the oxidation reaction and prevent cleavage of the DNA chain (Strömberg and Stawinski, 2004). Upon completion of this critical oxidation step, the DNA sequence is exposed to concentrated aqueous ammonia in order to cleave all nucleobase protecting groups and release the native DNA sequence from the CPG support.

Over the years, several reagents have been proposed for the activation of protected deoxyribonucleoside *H*-phosphonate monoesters (Strömberg and Stawinski, 2004); pivaloyl chloride (Froehler and Matteucci, 1986) and adamantoyl chloride (Andrus *et al.*, 1988) have remained the most popular activators for solid-phase synthesis of DNA sequences via the *H*-phosphonate approach. Although a capping step appears unnecessary to prevent extension of unphosphorylated shortmers, the incorporation of a capping reaction into the *H*-phosphonate synthetic protocol has been shown to potentially improve the overall performance of the method. The capping procedure consists of performing an additional coupling reaction using isopropyl *H*-phosphonate after each nucleoside *H*-phosphonate coupling step (Andrus *et al.*, 1988). The solid-phase synthesis of DNA sequences, reaching 107 nucleobases in length, has been achieved using the *H*-phosphonate method (Froehler *et al.*, 1986). However, this approach to the synthesis of DNA sequences has limitations. As depicted in Scheme 5, premixing the deoxyribonucleoside *H*-phosphonate monoesters 21 with excess pivaloyl chloride leads to the formation of bis-acylphosphites (23) along with competing *O*-acylation of the 5'-hydroxyl of unphosphorylated DNA sequences, as a consequence of the slower phosphorylation kinetic of 23. Furthermore, because of the

Scheme 4 The *H*-phosphate approach to the solid-phase synthesis of DNA or RNA sequences. DMTr, 4,4'-dimethoxytrityl; CPG, controlled-pore glass; R¹, protecting group; Pv, trimethylacetyl; B^P, protected pyrimidine and purine nucleobases; B, thymine-1-yl/uracil-1-yl, cytosine-1-yl, adenine-9-yl, or guanine-9-yl.

iterative exposure to pivaloyl chloride during the course of solid-phase DNA synthesis, *P*-acylation of *H*-phosphonate functions, to produce 24, occurs and could become problematic (Strömberg and Stawinski, 2004).

As mentioned above, the most damaging reaction encountered during the aqueous oxidation of polynucleoside *H*-phosphonates is the alkaline hydrolysis of *H*-phosphonate diester linkages, which leads to chain cleavage. When taken together, these drawbacks contribute to decrease the efficiency of the *H*-phosphonate approach to the synthesis of DNA sequences. Nonetheless, one of the advantages of the *H*-phosphonate method relates to the oxidation reaction, which can be carried out under nonaqueous conditions. Oxidation of polynucleoside *H*-phosphonates with elemental sulfur in pyridine/carbon disulfide or with 3*H*-1,2-benzothiaseleno1-3-one in pyridine/triethylamine affords phosphorothioate or phosphoroselenoate DNA sequences (Agrawal and Tang, 1990; Stawinski and Thelin, 1994). Alternatively, oxidation of polynucleoside *H*-phosphonates with carbon tetrachloride in the presence of primary and secondary amines or alcohols produced DNA phosphoramidate or phosphotriester sequences (Froehler, 1986; Froehler *et al.*, 1988).

Although the phosphoramidite approach continues to be preferred for the solid-phase synthesis DNA sequences on the basis of higher stepwise yields and fewer side-products, the *H*-phosphonate approach is particularly well-suited for the synthesis of RNA and modified DNA sequences (Stawinski and Krazewski, 1998; Strömberg and Stawinski, 2004).

The Chemical Synthesis of Oligoribonucleotides via the Phosphoramidite Approach

Given the recent developments in RNA interference as a means to silence the expression of specific genes, the availability of rapid and efficient methods for the chemical synthesis of RNA sequences in sufficient quantity for pharmaceutical applications has become an urgent issue. Although the various steps involved in the chemical synthesis of DNA and RNA oligonucleotides are similar (Scheme 2), the sequence of deprotection steps for RNA oligonucleotides differs in that the 2'-hydroxyl protecting group must be removed last, under conditions that would not result in the formation of (2'→5')-internucleotidic phosphodiester linkages and/or RNA chain cleavage.

Scheme 5 Formation of side products during solid-phase oligonucleotide synthesis via the *H*-phosphonate approach. Figure 4 The *tert*-butyldimethylsilyl group for 2'-hydroxyl protection of ribonucleosides and their phosphoramidite derivatives. DMTr, 4,4'-dimethoxytrityl; B^P, protected pyrimidine and purine nucleobases.

The choice of a protecting group for the 2'-hydroxy function of ribonucleosides is clearly the most important decision to be made when undertaking the chemical synthesis of RNA sequences. The selected protecting group should optimally: (1) be easy to introduce; (2) remain completely stable until the final deblocking step of the fully assembled RNA sequence (Scheme 2); and (3) be totally removable under conditions that do not compromise the structural integrity of the RNA sequence. The main objective of this section is to report the most significant advances that have been made in the development of 2'-hydroxyl protecting groups for ribonucleosides as their ethers, acetals, and esters in the solid-phase synthesis of oligoribonucleotides.

Ether Protecting Groups

The tert-butyldimethylsilyl group

With the advent of the phosphoramidite method for solid-phase synthesis of oligodeoxyribonucleotides, the ribonucleoside phosphoramidites **25** ([Figure 4](#)) have been successfully employed in the total synthesis of a 77-nucleotide RNA sequence ([Ogilvie et al., 1988](#)). Although the *tert*-butyldimethylsilyl (TBDMS) group is still widely used for 2'-hydroxyl protection in the solid-phase synthesis of RNA sequences, it is not without limitations. The propensity of the TBDMS group to undergo (2' $\leftrightarrow$ 3')-isomerization during synthesis, purification, and isolation of 5'-O-DMTr-2'-O-

TBDMS-ribonucleosides (Damha and Ogilvie, 1993) is problematic, as it may lead to the production of isomeric 3'-O-TBDMS phosphoramidite impurities (26, Figure 4) during the preparation of 25. The incorporation of 26 into RNA sequences during solid-phase synthesis should be avoided as it would result in the formation of unwanted (2'→5')-internucleotidic linkages, which could negatively affect the efficiency of small interfering RNA (siRNA) sequences in silencing gene expression (Prakash *et al.*, 2006). The use of 2-cyanoethyl (*N,N*-diisopropyl)phosphoramidochloridite, 2,4,6-collidine, and *N*-methylimidazole has been found to not lead to detectable migration of the TBDMS group during preparation of the ribonucleoside phosphoramidites 25 (Scaringe *et al.*, 1990).

The removal of amino protecting groups from the nucleobases of 2'-O-TBDMS-protected oligoribonucleotides is also problematic given that concentrated aqueous NH₃ cannot be used at elevated temperature (55 °C) without causing premature deprotection of the 2'-O-TBDMS groups, which could result in internucleotide cleavages. The use of triethylamine trihydrofluoride (Gasparutto *et al.*, 1992; Westman and Strömberg, 1994) has been proposed for the removal of 2'-O-TBDMS groups from oligoribonucleotides. Because of its effectiveness and reliability, triethylamine trihydrofluoride is currently the most widely used reagent for this purpose. It should be noted that a 'one-pot' deprotection of 2'-O-TBDMS-protected RNA sequences using anhydrous methylamine and neat triethylamine trihydrofluoride (Bellon, 2000) has been developed to decrease the overall deprotection time of RNA sequences.

The coupling kinetics of the phosphoramidites 25 is notoriously sluggish, presumably because of the steric crowding created by the 2'-O-TBDMS group around the activated phosphoramidite function. More than 10 min is often required to produce satisfactory coupling efficiencies (> 98%). As for the activation of deoxyribonucleoside phosphoramidites, activators more powerful than 1*H*-tetrazole including 5-ethylthio-1*H*-tetrazole, 5-benzylthio-1*H*-tetrazole, and 4,5-dicyanoimidazole have been proposed for improving the coupling kinetics of ribonucleoside phosphoramidites. As discussed above in the previous section, the increased acidity of an activator may cause the premature cleavage of the 5'-O-DMTr group and double coupling of activated phosphoramidites within a given synthetic cycle could occur. This must be avoided in order to preserve the integrity of the RNA sequences. An alternate strategy for improving the coupling rates and coupling efficiencies of the ribonucleoside phosphoramidites 25 is to replace these monomers with the corresponding *N,N*-diethylphosphoramidites 27 (Figure 4) or other less sterically hindered phosphoramidites (28; Gasparutto *et al.*, 1992). Presumably because these ribonucleoside phosphoramidites are not commercially available, they have not been frequently used in solid-phase RNA synthesis.

The 2-cyanoethyl group

The 2-cyanoethyl group has been reported for the 2'-O-protection of suitably protected ribonucleosides and their 2'-O-(2-cyanoethyl) ribonucleoside phosphoramidite derivatives (29, Figure 5). The solid-phase synthesis of a 2'-O-cyanoethylated RNA sequence (21-mer) has been carried out using the

Figure 5 The 2-cyanoethyl group for 2'-hydroxyl protection of ribonucleosides and their phosphoramidite derivatives. DMTr, 4,4'-dimethoxytrityl; B^P, protected pyrimidine and purine nucleobases.

phosphoramidites 29 and 5-benzylthio-1*H*-tetrazole over a 10-min coupling time (Saneyoshi *et al.*, 2007).

Complete removal of the 2'-O-cyanoethyl groups from the RNA sequence is accomplished by treatment with *n*-Bu₄NF in THF/*n*-propylamine. Interestingly, fully or partially 2'-O-cyanoethylated RNA sequences induce the formation of relatively stable hybrids with complementary DNA or RNA sequences. Although 2'-O-cyanoethylated RNA sequences could have been suitable candidates for RNA interference applications, the results of such applications remain to be reported.

Acetal Protecting Groups

Unlike 2'-O-acyl or 2'-O-silyl-protecting groups, 2'-O-acetal functions do not migrate to vicinal hydroxy functions and are completely stable under the basic conditions usually used for the removal of nucleobase and internucleotide phosphate protecting groups. Such properties are attractive and have led to the widespread use of acetal groups for 2'-hydroxyl protection in the chemical synthesis of RNA sequences. A general limitation of these 2'-acetal protecting groups in RNA synthesis is their sensitivity to acidic conditions, which are routinely used for deblocking the 5'-O-DMTr or Px protective groups. Consequently, the development of 2'-acetal protecting groups should be carefully planned to minimize the inherent incompatibility with 5'-acid-labile protecting groups.

The 1-aryl-4-alkoxy piperidin-4-yl groups

The most noteworthy properties of the 1-(2-chloro-4-methylphenyl)-4-methoxypiperidin-4-yl (Ctmp), 1-(2-fluorophenyl)-4-methoxypiperidin-4-yl (Fpmp), and 1-(4-chlorophenyl)-4-methoxypiperidin-4-yl (Cpep) protecting groups (Lloyd *et al.*, 2000) are their stability under the relatively drastic acidic conditions required for the removal of 5'-DMTr or Px protecting groups and, paradoxically, their facile removal under mild acidic conditions in the final deblocking of RNA sequences. 2'-O-Ctmp-, 2'-O-Fpmp-, and 2'-O-Cpep-protected ribonucleosides have been prepared from suitably protected ribonucleosides and converted to their phosphoramidite derivatives 30, 31, and 32, respectively (Figure 6).

Activation of these phosphoramidites with 5-ethylthio-1*H*-tetrazole requires a 10–15 min coupling time; the need for such a long coupling reaction time underscores the importance of the steric bulk imparted by the 2'-hydroxyl protecting group on the coupling kinetics and coupling efficiencies of ribonucleoside phosphoramidites. The 2'-O-protected oligoribonucleotides provide stability against ubiquitous

Figure 6 The 1-aryl-4-alkoxypiperidin-4-yl groups for 2'-hydroxyl protection of ribonucleosides and their phosphoramidite derivatives. R, 4,4'-dimethoxytrityl (DMTr) or 9-phenyloxanthren-9-yl; B^P, protected pyrimidine and purine nucleobases.

Figure 7 The TOM group for 2'-hydroxyl protection of ribonucleosides and their phosphoramidite derivatives. DMTr, 4,4'-dimethoxytrityl; B^P, protected pyrimidine and purine nucleobases.

ribonucleases throughout purification and storage. When required, the 2'-O-Ctmp, -Fpmp, and -Cpep groups are removed from RNA oligonucleotides under carefully controlled acidic conditions to reduce both (2' ↔ 3')-isomerization and the cleavage of internucleotidic phosphodiester linkages to a negligible extent. As eluted above, the Cpep group has been found to be more stable to acidic hydrolysis at pH 0.5 than either 2'-O-Ctmp or 2'-O-Fpmp and more labile to acidic hydrolysis at pH 3.75 than either of the latter, therefore allowing milder deprotection conditions (Lloyd *et al.*, 2000).

The large-scale synthesis of 2'-O-Cpep ribonucleosides and that of their phosphoramidite derivatives 32 has been reported as being cost-effective (Pon *et al.*, 2005) and therefore may offer a budgetary incentive over other ribonucleoside phosphoramidites when undertaking the large-scale preparation of siRNA sequences.

The triisopropylsilyloxymethyl group

The inherent flexibility of formaldehyde acetal linkers has been exploited to improve the coupling rates and coupling efficiencies of those ribonucleoside phosphoramidites, which have their 2'-hydroxy functions blocked with bulky groups. An example of this synthetic strategy relates to the development of the triisopropylsilyloxymethyl (TOM) group (Pitsch *et al.*, 2001), as an alternative to the TBDMS group for protection of the 2'-hydroxy functions of ribonucleosides and their phosphoramidite derivatives (Figure 7). One advantage of the 2'-O-TOM over the 2'-O-TBDMS group is that it does not undergo (2' ↔ 3')-isomerization during synthesis, purification, and isolation of 2'-O-TOM ribonucleosides (33) and their 5'-protected 2'-O-TOM phosphoramidite derivatives (34).

The high isomeric purity of 34 imparts correspondingly high integrity of the (3' → 5')-internucleotide linkages throughout RNA chain assembly. The coupling efficiency of the ribonucleoside phosphoramidites 34 is optimal when activated with 5-benzylthio-1H-tetrazole over a coupling time of 3–4 min. Under these conditions, coupling efficiencies >99% are achieved in the preparation of 40–84-nucleotide long RNA sequences on CPG supports. Removal of the nucleobase and phosphate protecting groups under basic conditions also releases the 2'-O-TOM-protected RNA sequences from the CPG supports. The 2'-O-TOM groups are removed from the RNA sequences by treatment with *n*-Bu₄NF•3H₂O or Et₄NF•3H₂O in DMSO, DMF or 1-methylpyrrolidin-2-one (Pitsch *et al.*, 2001). By virtue of the stability of the 2'-O-TOM group to a variety of reagents and reaction conditions and the commercial availability of 34, the use of these phosphoramidite monomers is still, nowadays, very popular for the preparation of native and modified RNA sequences (Porcher and Pitsch, 2005).

The 2-cyanoethoxymethyl group

A remarkable method for the solid-phase synthesis of oligoribonucleotides has emerged with the development of the 2'-O-(2-cyanoethoxymethyl) (CEM) ribonucleosides 35 (Figure 8) and their 5'-protected 2'-O-CEM phosphoramidite derivatives 36 (Shiba *et al.*, 2007).

These phosphoramidite monomers are particularly efficient at low concentration (0.05 M) in the solid-phase synthesis of oligoribonucleotides. Mixed-nucleobase RNA sequences of up to 170 nucleobases in length have been prepared on a CPG support with a pore size of 2000 Å (Nagata *et al.*, 2010). Activation of the phosphoramidites 36 is effected using 5-

Figure 8 The 2-cyanoethoxymethyl group for 2'-hydroxyl protection of ribonucleosides and their phosphoramidite derivatives. DMTr, 4,4'-dimethoxytrityl; B^P, protected pyrimidine and purine nucleobases.

Figure 9 The bis-(2-acetoxyethoxy)methyl group for 2'-hydroxyl protection of ribonucleosides and their phosphoramidite derivatives. B^P, protected pyrimidine and purine nucleobases.

benzylthio-1*H*-tetrazole in acetonitrile over a period of 150 s. The modest sensitivity of the 2'-O-CEM group to the basic conditions used for nucleobase and phosphate deprotection and release of the 2'-O-CEM protected RNA sequences from the CPG support is noteworthy. Less than 5% of the 2'-O-CEM groups are removed on exposure to ethanolic ammonium hydroxide. Removal of the 2'-O-CEM group from the RNA sequence is effected by treatment with *n*-Bu₄NF in DMSO and nitromethane at ambient temperature. The use of 2'-O-CEM protection in the synthesis of a pyrophosphorylated 130-mer has led to, after enzymatic addition of a 5'-cap and a 3'-poly (A) tail, the unprecedented preparation of an artificial mRNA, which has been shown to support protein synthesis in a cell-free system (Nagata *et al.*, 2010).

Orthoester and Ester Protecting Groups

The bis-(2-acetoxyethoxy)methyl group

The use of the bis-(2-acetoxyethoxy)methyl (ACE) orthoester group for the protection of the 2'-hydroxy functions and the use of a silyl ether group for protection of the 5'-hydroxy function of ribonucleosides in solid-phase RNA synthesis has been reported (Scaringe, 2001, 2004). Conversion of the 2'-O-ACE-protected ribonucleosides 37 to 5'-silylated 2'-O-ACE-protected ribonucleoside phosphoramidites 38 (Figure 9) is achieved in two steps upon reaction with bis-(*N,N*-

diisopropylamino)methoxyphosphine in the presence of a catalytic amount of 1*H*-tetrazole. The solid-phase synthesis of 2'-O-ACE-protected RNA sequences is performed on a polystyrene support functionalized with an appropriate 2'-O-ACE-protected ribonucleoside 3'-O-hemisuccinate ester because CPG supports are not compatible with the iterative triethylamine trihydrofluoride-assisted 5'-O-desilylation reaction that is required for chain extension.

In this regard, commercial DNA/RNA synthesizers must be modified to accommodate the use of triethylamine trihydrofluoride formulations for 5'-O-desilylation reactions (Scaringe, 2001). The phosphoramidites 38 are activated with 5-ethylthio-1*H*-tetrazole and the coupling time is set to not exceed 90 s. Under these conditions, average coupling yields exceeding 99% are achieved; the oxidation of each phosphite triester linkage is effected by treatment with *tert*-butyl hydroperoxide. The solid-phase-linked RNA sequences are then exposed to disodium 2-carbamoyl-2-cyanoethylene-1,1-dithiolate (Dahl *et al.*, 1990) in DMF for complete removal of the methyl groups protecting the internucleotidic phosphate linkages while leaving the oligoribonucleotides attached to the polystyrene support. Aqueous MeNH₂ is then used to cleave the amino protecting groups of the nucleobases, deacylate the 2'-O-ACE-functions, and release the 2'-O-protected RNA sequences from the solid support. A particular advantage of the ACE-protecting group is that the removal of its two acetyl groups increases the water solubility of the still 2'-protected

Figure 10 The pivaloyloxymethyl group for 2'-hydroxyl protection of ribonucleosides and their phosphoramidite derivatives. DMTr, 4,4'-dimethoxytrityl; B^P, protected pyrimidine and purine nucleobases.

RNA sequences. It should be noted that the resulting 2'-O-[bis-(2 hydroxyethyl)]methyl protecting groups are an order of magnitude more labile to acidic hydrolysis than the original ACE groups. Thus, complete cleavage of the 2'-O-protecting groups from the RNA sequences is achieved in a TEMED-acetate buffer solution (pH 3.8) at 60 °C (Scaringe, 2001).

The introduction of 5'-O-silyl-2'-O-ACE-protected ribonucleoside phosphoramidites **39** (Figure 9) with a visible chromophore appended to the 5'-silyl-protecting group allows for measurements of coupling efficiencies throughout the chain assembly process (Delaney *et al.*, 2008). It should be pointed out that the use of 5'-silylated 2'-O-ACE-protected ribonucleoside phosphoramidites in solid-phase RNA synthesis is one of the very best strategies for the preparation of high purity RNA sequences.

The pivaloyloxymethyl group

The base-labile pivaloyloxymethyl (PivOM) group has been proposed for the protection of 2'-hydroxy functions of ribonucleosides (Lavergne *et al.*, 2008, 2010). 5'-Protected 2'-O-PivOM ribonucleosides **40** (Figure 10) are prepared as a mixture of regioisomers. The chromatographically purified ribonucleosides **40** are converted to their phosphoramidite derivatives **41** under standard phosphitylation conditions.

These phosphoramidites have been employed in the solid-phase synthesis of chimeric RNA/DNA sequences of up to 21 nucleobases in length. The phosphoramidites **41** are activated with 5-benzylthio-1*H*-tetrazole and coupling efficiencies of >99% have been obtained within a coupling time of 3 min. The solid-phase bound chimeric RNA sequences are exposed to an acetonitrile solution of 1,8-diazabicyclo-[5.4.0]undec-7-ene to remove the 2-cyanoethyl phosphate protecting groups. In a second step, a 28% aqueous ammonia solution is used over a limited period of time (3–5 h) to remove the acyl groups protecting the nucleobases and the 2'-O-PivOM groups while releasing the chimeric RNA sequences from the CPG support. It has been claimed that the 2'-O-(hydroxymethyl) groups remain intact in aqueous ammonia solution, thereby preventing degradation of the fully deprotected RNA sequences under these basic conditions. It is however recommended that isopropylamine be added to these solutions, prior to evaporation to dryness, in order to avoid a reaction between the guanine residues and formaldehyde that is produced from the cleavage of the 2'-hemiacetal functions (Lavergne *et al.*, 2010). No chain cleavage, base modification and presence of unnatural internucleotidic phosphodiester linkages have been detected under these conditions. Crude chimeric RNA sequences are obtained in high yields and high purity.

DNA and RNA Microarrays

DNA Microarrays

Although synthetic DNA oligonucleotides and genes have become widespread, the costs associated with the production of these biomolecules remain high with limited throughput. DNA microarrays have attracted considerable attention as they are recognized as abundant sources of inexpensive oligonucleotides for the construction of synthetic genes. Unlike conventional solid-phase oligonucleotide synthesis on CPG-filled columns, DNA microarray synthesis technologies utilize the surface of a silicon chip or a glass slide, with oligonucleotide growth confined to addressable surface locations. A variety of techniques including photolithography with physical or digital masks, inkjet printing, and electrochemical methods were used in the production of DNA microarrays for high-throughput identification and quantification of nucleic acids, monitoring gene expression or total gene assembly. These methods will be reviewed in this report.

Photolithography with physical or digital masks

The surface of a glass slide is commonly used for the covalent attachment of oligonucleotides; the glass surface is functionalized with a hydroxylalkylated linker (McGall *et al.*, 1996), which upon reaction with any deoxyribonucleoside phosphoramidites (42) bearing 5'-photolabile protecting groups (Figure 11), sets the stage for photolithographic DNA synthesis (Beier *et al.*, 2001).

A stack of masks needs to be prefabricated based on the oligonucleotide sequences to be synthesized on the arrays. These masks define the areas on the glass slide that need light exposure to remove the 5'-photolabile blocking groups and enable the free 5'-hydroxyl to react with an activated phosphoramidite monomer (Fodor *et al.*, 1991). Mask replacements and synthetic cycles are repeated until the DNA chain

assemblies are completed. This technology has been applied to the production of high-density probe arrays for gene expression and nucleic acid sequence analysis (McGall *et al.*, 1996). It should however be pointed out that the use of large numbers of prefabricated photomasks is costly. A relatively low-cost alternative to the use of physical masks is the maskless digital photolithographic method (Singh-Gasson *et al.*, 1999) using the Digital Light Processing technology (Richmond *et al.*, 2004). This method involves a reflective display device consisting of an electromechanically controlled array of micro-mirrors. This technology is easily programmable and very flexible; high resolution, precisely controllable light patterns can be generated in an automated manner. Scheme 6 illustrates a typical DNA synthesis cycle in maskless light-directed production of microarrays using the deoxyribonucleoside phosphoramidites 42 on an amine-derivatized glass slide that is functionalized with a leader nucleoside 43 through a base-labile linker. The DNA synthetic cycle follows the following order: (1) 5'-photodeprotection of 43 to 44, (2) coupling, (3) capping, and (4) 5'-photodeprotection.

An oxidation reaction is not required in each cycle because 5'-photodeprotection does not cleave oligonucleotides at the phosphite ester linkages, thereby allowing intermittent or a single final oxidation step. The coupling reaction consists of activating the phosphoramidites 42 with 4,5-dicyanoimidazole in acetonitrile over a period of 30–150 s. Under these conditions, the phosphoramidite coupling efficiency approaches 99%. A capping step, using an appropriate anhydride and 1-methylimidazole, is then performed and is followed by a drying step using helium, which has been found to improve the photodeprotection step by clearing fluid out of the delivery and waste lines. 5'-Photodeprotection of the 2-(2-nitrophenyl)propyloxycarbonyl group is performed using near ultraviolet light (365 nm) in the presence of an organic base. A single exposure to aqueous iodine is usually sufficient to convert all phosphite triester linkages to their corresponding phosphate triesters. Upon completion of microarray synthesis, the nucleobase and phosphate protecting groups are removed by immersing the array in an ethanolic solution of ethylenediamine or aqueous ammonia solution (Richmond *et al.*, 2004), which also releases the DNA sequences from the glass surface depending on the nature of the linker anchoring the DNA sequences to the surface of the array.

Maskless array synthesis is an efficient and versatile method for synthesizing high-density arrays of DNA sequences for hybridization and other molecular binding-based experiments. For applications requiring high DNA sequence purity, such as gene assembly, unintended deprotection due to light scattering and diffraction leads to sequence insertion errors, which contribute significantly to the overall error rate. However, these complications can be reduced with straightforward experimental strategies (Agbavwe *et al.*, 2011).

Inkjet printing

Piezoelectric inkjet oligoarray synthesis (Blanchard *et al.*, 1996) is a particularly versatile method that allows for rapid construction of oligonucleotide arrays containing any desired sequences. By dispensing deoxyribonucleoside phosphoramidite monomers from a multichannel inkjet print head,

large numbers of sequences can be chemically synthesized in parallel. *De novo* oligonucleotide synthesis using a piezoelectric inkjet oligoarray synthesizer overcomes several of the problems inherent to conventional photolithographic mask arrays. DNA synthesis using the inkjet mechanism has been demonstrated with microfabricated piezoelectric inkjet pumps (Blanchard *et al.*, 1996); the inkjet head has six fluid channels, four of which delivering phosphoramidite precursors, one for an activator, and another one for an optional linker or modified nucleobase. The use of commercial deoxyribonucleoside phosphoramidites and reagents that are essentially the same as those employed for standard solid-phase DNA synthesis underscores the versatility of the method. Although, acetonitrile is the preferred solvent for deoxyribonucleoside phosphoramidites, this solvent is not suitable for inkjet printing due to its high volatility; droplets may even evaporate before contact with the slide surface. Furthermore, phosphoramidite precipitates can accumulate on the print head and clog the nozzles. To minimize evaporation of picolitre-sized droplets during printing, the selection of a suitable solvent is critical. A 1:1 solution of methyl glutaronitrile and 3-methoxypropionitrile had the most favorable combination of volatility, solubility, surface tension, and synthesis parameters. The solution readily dissolves phosphoramidite monomers and produces coupling efficiencies similar to those measured when using acetonitrile during routine solid-phase synthesis of DNA sequences up to 60 nucleobases in length; a 1×3 in glass slide contains about 185 000 DNA sequences. The inkjet printing method for microarray synthesis has mainly been developed and used for gene-expression profiling and comparative genomic hybridization applications (Wolber *et al.*, 2006).

Aside from the above technologies that have been used for the preparation of DNA microarrays, a number of other methods have been developed using either electrochemical (Egeland and Southern, 2005; Chow *et al.*, 2009) or microfluidic (Moorcroft *et al.*, 2005; Hua *et al.*, 2006; Huang *et al.*, 2007) devices for microscale parallel DNA synthesis.

Electrochemical arrays

Microelectrodes are employed to induce electrochemical reactions resulting in the production of an acid, which is required to iteratively deblock the 5'-DMTr groups of growing DNA chains (Egeland and Southern, 2005). The acid is produced only at specified sites by electrochemical oxidation of hydroquinone using individually addressable microelectrodes. As shown in Figure 12, the diffusion of the acid to its intended location on the DNA array is controlled by an adjacent cathode, which prevents the 5'-DMTr deblocking of neighboring sites by consuming any diffused acid.

Deoxyribonucleoside phosphoramidites are then added for DNA chain extension leading, after multiple synthesis cycles, to the construction of different DNA sequences on the array. The synthesis of only short DNA sequences has been successfully achieved on electrochemical arrays. A fundamental technical limitation of electrochemical DNA synthesis is the amount of acid produced after application of current to the microelectrodes; too much or too little acid-mediated deblocking, over multiple couplings, has a dramatic effect

Scheme 6 Synthesis of DNA oligonucleotides on glass surfaces using deoxyribonucleoside phosphoramidites with 5'-photolabile protecting groups. Nppoc, 2-(2-nitrophenyl)propyloxycarbonyl; DCI, 4,5-dicyanoimidazole; B^P, protected pyrimidine and purine nucleobases; B, thymine-1-yl, cytosine-1-yl, adenine-9-yl, or guanine-9-yl.

Figure 12 Illustration of an electrochemical DNA microarray. The synthesis solutions include a solution of hydroquinone and a solution of benzoquinone in acetonitrile. Anodic oxidation of hydroquinone produces acid, which migrates downward toward the array of pre-attached 5'-DMTr-protected deoxyribonucleosides and cleaves the DMTr groups (orange-colored areas). Acid that migrates sideways undergoes cathodic reduction to regenerate benzoquinone. Free 5'-hydroxyls are then exposed to activated deoxyribonucleoside phosphoramidites to extend the growing DNA chains. R, 4,4'-dimethoxytrityl (DMTr).

on the yields and integrity (depurination) of long DNA sequences.

Gene assembly from DNA microarrays

Successful attempts have been made to use oligonucleotides synthesized from DNA microarrays as building blocks for gene assembly. The use of cleavable linkers for anchoring the DNA sequences to the surface of the arrays are necessary to permit, when needed, the release of these DNA sequences from the arrays (Richmond *et al.*, 2004). For this purpose, a treatment with aqueous ammonia is adequate for complete deprotection and release of the DNA sequences from the surface of the arrays. The DNA sequences are then collected as a pool and used for downstream processing. Typically, 10^3 – 10^6 different DNA sequences can be synthesized on microarrays, albeit in

low yields ($\sim 10^6$ molecules of each DNA sequence); a pre-amplification of the DNA sequences is necessary to produce an optimal concentration of the sequences for a gene assembly reaction. In order to accommodate post-synthesis enzymatic amplification, the DNA sequences should have been designed to include short universal PCR primers, flanking each sequence. After amplification, the primers must be removed using appropriate restriction enzymes. Erroneous DNA sequences produced from array-synthesized and PCR-amplified oligonucleotides must be removed from the correct DNA sequences using hybridization arrays constructed with short DNA oligonucleotides complementary to the pool of DNA sequences earmarked for gene construction. After stringent hybridization and washes, the correct DNA sequences are sufficiently enriched for use in gene assembly (Tian *et al.*,

2004). A DNA microarrays with 10^3 – 10^6 different DNA sequences can lead to the construction of sequences equivalent to the 582 970 base pair genome of *M. genitalium* (Gibson *et al.*, 2008). Thus, the availability of synthetic DNA sequences has already and will continue to revolutionize molecular biology and bioengineering.

Microfluidics

Ultraviolet light-emitting diode-mediated DNA synthesis in glass capillaries

As an alternative to digital photolithography, the use of microfluidic devices for microscale parallel DNA synthesis has been proposed (Blair *et al.*, 2006). The synthesis of DNA strands inside hydroxyalkylated glass capillaries has been carried out using ultraviolet light-emitting diodes (LEDs) and photolabile deoxyribonucleoside phosphoramites (42). Through synchronization of fluid delivery and UV light emission from each LED, discrete DNA sequences are grown

on the inner surface of the capillary at the location of each LED (Figure 13).

A typical DNA synthesis cycle requires 180 s for photo-deprotection and 60 s for phosphoramidite coupling. After synthesis, the DNA sequences are deprotected by immersing the capillary in an ethanolic solution of ethylenediamine. Multiple oligonucleotides of up to 70 nucleobases in length have been synthesized in single capillaries and characterized by hybridization, sequencing, and gene synthesis. The DNA sequences have been demonstrated to be of high quality (up to 44% perfect sequences).

RNA microarrays

Over the past two decades, noncoding RNAs such as micro-RNAs, small interfering RNAs, and riboswitches have been reported to play important roles in various biological events by regulating gene expression. These events include development, differentiation, and metabolism. In this context, RNA aptamers and ribozymes have found applications in therapy and diagnostics, synthetic biology, and biosensors. With the objective to better understand the functions of these RNAs, it has become imperative to employ microarray technologies for high-throughput analysis of functional RNAs. The construction of RNA microarrays can be divided into three types. The first type involves the direct attachment of chemically modified RNA onto an appropriate surface; the immobilization of biotinylated RNA aptamers onto a streptavidin-coated glass slide (Collett *et al.*, 2005) provides an example of this type of microarrays for the detection of specific proteins. Alternatively, thiol-modified RNAs onto a gold-coated or maleimide-functionalized glass plates have been prepared for ultrasensitive detection and analysis of target DNA molecules using RNase H as an amplification tool (Goodrich *et al.*, 2004).

The second type of RNA microarrays relates to a method consisting of arraying various unmodified RNA sequences through ligation with the 5'-phosphate function of identical pre-arrayed DNA sequences on a gold surface using T4 RNA ligase. This method has been used to produce a five-component RNA microarray of potential aptamers for protein factor IXa (Figure 14). Surface plasmon resonance imaging (SPRI) measurements have been used to correctly identify the best aptamer to protein factor IXa; the structure of this aptamer has previously been determined from systematic evolution of ligands by exponential enrichment (SELEX) measurements (Li *et al.*, 2006).

The third type of RNA microarrays is an extension of the second type and is aimed at generating RNA sequences from the T7 RNA polymerase transcription of double-stranded DNAs attached to gold thin films in a microfluidic format (Figure 15). The RNA sequences diffuse, as they are synthesized in the microfluidic channel, and are captured by hybridization onto adjacently arrayed single-stranded DNA sequences complementary to the 5'-end of the RNA aptamer sequences (Chen *et al.*, 2012).

SPRI is then used to measure the bioaffinity of RNA aptamers for protein biomarkers. This method allows for the concurrent fabrication of multiple RNA sequences that can hybridize simultaneously to distinct anchored DNA sequences to produce a multiplexed RNA aptamer microarray.

Figure 13 UV-LED-mediated DNA synthesis in glass capillaries. Selected regions of a glass capillary are illuminated by LEDs. The UV light emitted by each LED deprotects the 5'-hydroxyls of DNA strands covalently attached to the inside of the capillary through hydroxyalkylated linkers. Photolabile deoxyribonucleoside phosphoramites (42) are used for iterative DNA chain extension. LED, light-emitting diode. A scalable method for multiplex LED-controlled synthesis of DNA in capillaries. *Nucleic Acids Research* 34, e110 with permission from Oxford University Press.

The *in situ* synthesis of RNA microarrays is considerably more problematic than that of DNA microarrays. However, in spite of challenging difficulties, rU₁₂ and rA₁₂ have been synthesized *in situ* on a glass surface using a maskless photolithographic array synthesizer and 5'-O-[2-(2-nitrophenyl)

propyloxycarbonyl] ribonucleoside phosphoramidites (45 and 46, Figure 16).

These phosphoramidites monomers are activated with 4,5-dicyanoimidazole in acetonitrile over a coupling time of 10–15 min. The standard capping reaction with acetic anhydride is performed and is followed by an aqueous iodine oxidation. The 5'-photolabile protecting group is iteratively cleaved upon exposure to UV light (365 nm). In order to determine coupling efficiencies, the RNA sequences are terminally labeled through a Cy3 phosphoramidite coupling reaction. On the basis of fluorescence intensity measurements, the coupling efficiency of 45 and 46 averaged 96% (Lackey *et al.*, 2009). Deprotection of rA₁₂ consisted of immersing the synthesized microarrays in an acetonitrile solution of triethylamine to remove the 2-cyanoethyl phosphate protecting groups; the levulinyl group protecting the nucleobase and 2'-O-acetal function of adenosine residues are subsequently cleaved under hydrazinolytic conditions. One important advantage, this method has over all other methods used for the fabrication of RNA microarrays, is that the removal of the

2'-hydroxyl protecting group can be efficiently performed on the array, when needed. This feature minimizes the potential for degradation of the RNA sequences by ubiquitous RNases. Although this approach to the preparation of RNA microarrays has not as yet been extended to the *in situ* synthesis of RNA sequences with mixed nucleobases, this work represents a step in the right direction for the construction of RNA microarrays dedicated to the analysis of RNA aptamers as well as RNA-protein and RNA-RNA interactions of biological significance.

Concluding Remarks

The chemical synthesis of DNA and RNA sequences has had and will continue to have a positive influence on the development of nucleic acids-based drugs for the treatment of cancer and infectious diseases. Furthermore, with the use of array-derived oligonucleotides and the ability to synthesize longer DNA sequences, one might expect those technologies to have a wide range of applications in high-throughput genomics, biodetection, and synthetic biology in the context of gene assembly and genome constructs, which should benefit all areas of molecular biology.

Glossary

Baculovirus Member of a family of DNA viruses infectious to invertebrates. In the field of recombinant protein expression this usually refers to isolates of *Autographa californica* multiple nuclear polyhedrosis virus (AcMNPV).

Episomal Referring to DNA fragments that are replicated and maintained extrachromosomally.

Heterologous protein Protein derived from an alternative organism or source to the chosen expression host.

Hypothermic shift A technique whereby the temperature of incubation is dropped below the standard used for growth. Reduction of the temperature has a negative effect on cell growth/division, but may have a positive effect on protein expression.

Overview of Expression Systems

Expression systems are used to express proteins that are used in a range of methods ranging from structural biology to *in vivo* studies or as therapeutic agents. An expression system essentially consists of three different components necessary for the production of recombinant proteins. Firstly, a biological environment, most often a cell, is used to provide energy and machinery for protein synthesis. It is also possible to use cellular extracts containing the necessary components, i.e., cell-free protein expression systems. Secondly, a vector that facilitates the introduction of genetic material into the cell; containing regulatory parts that provide for replication of the genetic material and usually selection markers for

maintenance. Lastly, the expression cassette, which is incorporated into the vector that contains the open reading frame encoding the amino acid sequence for the protein to be expressed. The expression cassette also contains all the components necessary for transcription and translation of the protein to be produced (**Figures 1 and 3**).

The expression host can be anything that has the necessary framework to produce protein from the genetic material provided. A large variety of organisms are used for the production of proteins, even transgenic animals or plants are used for protein production (Houdebine, 2009; Egelkrout *et al.*, 2012; Berlec and Strukelj, 2013). In this overview we focus on systems that are commonly used in a research setting, which are most commonly cellular systems (**Table 1**). A special

Table 1 Characteristics of common expression systems

Expression host		Transcription regulation (inducer)	Doubling time (h)	Vectors	Glycosylation	PTM	Common use
Bacteria (simple, robust, lowest cost)	<i>Escherichia coli</i>	PT7, Ptac (IPTG)	0.3–0.5	Plasmid (episomal)	No	No	Small proteins Single domains Antigens
	Other Enterobacteria	PBAD (arabinose) PL (switch to 42 °C) Ptac (IPTG) PalkBp (sodium salicylate) Pm/xyIS (toluinic/benzoic acid) PxylA (xylose) PT7 (IPTG)	1.0–2.0	Plasmid (episomal)	No	No	Specific receptors Fimbrial proteins Heme proteins
	Firmicutes	<i>Bacillus</i> spp.	0.6–1.0	Plasmid (episomal)	No	No	Secreted enzymes Virulence factors
	Unicellular fungi (yeast)	PAOX1 (methanol) PFLD (acetamide) PGAP (constitutive)	1.5–3.0	Plasmid (integrative)	High	Some	Secreted proteins Complement factors Membrane proteins Peroxisome proteins Kinases
Eukarya (glycosylation, PTMs)	Non-methylotrophic (<i>Saccharomyces cerevisiae</i> , <i>Kluyveromyces fragilis</i>)	PGAL1/PGAL10 (galactose) Acetamidase (acetamide) Glycolytic (constitutive)	1.3–2.0	Plasmid (episomal/integrative)	High	Some	Nuclear proteins
	Filamentous fungi	<i>Aspergillus</i> spp. <i>Hypocrea</i> <i>Trichoderma</i> spp.	3.0–4.0	Plasmid (episomal/integrative)	High	Some	Membrane proteins Antibodies Secreted enzymes Glycoenzymes
	Protozoa	<i>Leishmania tarentolae</i>	6.0–13	Plasmid (integrative)	Complex	High	General purpose
	Insect cells	Sf9, Sf21, High Five™ BTI-TN-5B1-4, S2	16–72	Plasmid (episomal) Virus	Complex	Yes	General purpose
Mammalian cells		pMT (copper/cadmium) pAc5 (constitutive) SV40, CMV (constitutive)	14–36	Plasmid (episomal/integrative) Virus	Complex	Yes	Secreted proteins Antibodies

Figure 1 Schematic of pET-15b used as a vector for heterologous protein expression in *E. coli*. (a) The *lacI* gene provides repressor protein to titrate the *lac* operator controlling expression from the T7 promoter. For selection the plasmid contains the *bla* gene encoding beta-lactamase providing resistance to ampicillin. Also depicted is the position of the origin of replication (ColE1 pMB1) and the expression cassette. (b) Contents of the expression cassette in pET-15b. T7 RNA polymerase initiates transcription at the T7 promoter. Additional control of transcription is provided by the *lac* operator where binding of *lac* repressor prevents transcription from the T7 promoter. The ribosome-binding site is located upstream of the open reading frame containing the protein coding sequence between the start and stop codons. The expression cassette ends with the T7 transcription termination sequence where T7 RNA polymerase stops and dissociates from the plasmid DNA sequence.

case is the cell-free expression systems that are described in a separate section. Hosts are commonly divided into prokaryotic or eukaryotic since it broadly describes the characteristics of the expression system. For detailed properties of each system, read the subsequent sections detailing the different host systems.

The most commonly used vector for recombinant protein expression is plasmid DNA. Many organisms carry plasmids which are extrachromosomal, self-replicating, circular pieces of DNA. Plasmids are used as vectors to introduce genetic material since they can be readily purified, manipulated, and re-introduced into several host organisms. Other vectors that can be used to carry the genetic information required to guide protein production are viruses or linear DNA fragments.

Bacterial Expression Systems

Bacterial expression systems are used for their ease of genetic manipulation, rapid growth, and the ability to grow in low cost, complex, or chemically defined media. The gram-negative bacterium *Escherichia coli* is widely used for recombinant protein production. *E. coli* has been used as a model organism

for over 60 years and besides the complete characterization of its genome sequence there is also a wealth of knowledge about its biochemistry and molecular biology. A couple of years after the start of the molecular biology revolution in the 1970s it was the first host for heterologous protein expression (Cohen *et al.*, 1973) and it is still one of the most important organisms for recombinant protein production. In *E. coli* the recombinant gene is almost always expressed from a plasmid and not stably integrated into the host cell chromosome. The common features present in a plasmid used for recombinant protein expression in *E. coli* are shown in Figure 1.

The number of plasmid copies within the cell can range from one to several hundreds. The copy number of plasmids is a combined property of the replicon present in the plasmid, the cell, and its current metabolic state. The ColE1-family of replicons are used in popular vectors system such as pET (pMB1, 15–60 copies/cell) and pUC (pMB1 variant, 500–700 copies/cell). Gene expression can be dependent on gene dosage although it is much more common that the limiting factor for protein production is in processes downstream of transcription (Novoa and Ribas de Pouplana, 2012; Gustafsson *et al.*, 2012). A very high plasmid copy number and high level of transcription will impose a metabolic burden on the cells

Table 2 Solubility-enhancing protein domains

Tag	Protein and source organism	Mw (kDa)	IEP
PDI	Protein disulfide isomerase (<i>Homo sapiens</i>)	55.4	4.4
NusA	N-utilization substance (<i>E. coli</i>)	54.9	4.3
MBP ^a	Maltose-binding protein (<i>E. coli</i>)	40.8	5.0
T7PK	N-terminal domain of T7 protein kinase (Bacteriophage T7)	27.6	4.5
GST ^a	Glutathione-S-transferase (<i>Schistosoma japonicum</i>)	25.5	6.5
DsbC	Protein disulfide isomerase (<i>E. coli</i>)	23.5	6.3
IF2 I	N-terminal domain of initiation factor 2 (<i>E. coli</i>)	17.7	9.8
ZZ ^a	Protein A IgG binding double domain (<i>Staphylococcus aureus</i>)	14.5	4.6
SUMO	Small ubiquitin like modifier (<i>H. sapiens</i>)	10.9	5.0
Trx	Thioredoxin (<i>E. coli</i>)	11.8	4.6
Ub	Ubiquitin (<i>H. sapiens</i>)	8.6	7.5
GB1 ^a	Protein G Ig binding domain B1 (<i>Streptococcus</i> sp.)	6.5	4.4
Rbx	Rubredoxin (<i>Thermotoga maritima</i>)	6.0	3.9

^aThese tags can also be used for direct affinity purification without adding an additional affinity tag.

Note: Solubility-enhancing domains including their molecular weight (Mw) and isoelectrical point (IEP) calculated from the native tag sequence without any adjacent amino acids.

lowering the growth rate, rate of translation and hence negatively influence the production of the recombinant protein. Common alternative replicons that are present at lower copy number and do not belong to the same incompatibility group are p15A (~10 copies/cell) and pSC101 (~5 copies/cell).

Recombinant gene expression in *E. coli* is normally under the control of an inducible promoter that requires the presence of a specific metabolite or synthetic inducer to direct transcription of the gene of interest. Several different promoters are in use with the most common being lac/tac, lacUV5, araBAD, and rhaBAD (Lutz and Bujard, 1997; Guzman *et al.*, 1995; Giacalone *et al.*, 2006).

For the popular pET expression system in *E. coli*, the expression induced by the addition of inducer is not of the actual recombinant gene but instead of a viral RNA polymerase from bacteriophage T7 that in turn recognizes the promoter controlling the recombinant gene. The T7 RNA polymerase, present in the IDE3 prophage integrated into the bacterial chromosome of the commonly used BL21(DE3) strain, is under the control of a lacUV5 promoter. Upon induction with lactose or isopropyl- β -D-1-thiogalactopyranoside (IPTG; a synthetic, non-metabolizable lactose analogue) the expressed T7 RNA polymerase will recognize the strong T7 promoter which controls recombinant gene expression on the introduced plasmid (Studier, 2005). The main benefit of this system is very strong transcription of the recombinant gene, since the T7 RNA polymerase has very high processivity and only recognizes the T7 promoter present in the pET plasmid and not endogenous promoters in *E. coli* (Studier *et al.*, 1990).

Heterologous protein production of eukaryotic genes in *E. coli* (and other prokaryotes) has a potential drawback as many posttranslational modifications present in eukaryotes are not performed in these organisms (including glycosylation, myristylation, isoprenylation, and amidation). The bacteria have a reductive environment in the cytoplasm preventing formation of disulfides necessary for the structure of many extracellular proteins from eukaryotes. It is also frequently seen in bacteria that the protein is expressed in intracellular aggregates called inclusion bodies. These inclusion bodies can be isolated, denatured, and then refolded to produce protein that is active

and of the correct conformation. This process has been used extensively in the past to produce small, single domain proteins and also with some success for larger, disulfide-bonded proteins (Mayer and Buchner, 2004). But from an expression standpoint, inclusion body formation is most often to be avoided due to the extra effort required to obtain functional proteins in their native state. There are a number of strategies described to increase the amount of soluble recombinant protein produced (Correa and Opezzo, 2015). Methods to reduce inclusion body formation include techniques that reduce the rate of protein translation (reduced growth temperatures or weaker induction of expression) or improve the folding of the recombinant protein by co-expression of chaperones. Another very common strategy to both increase the overall yield but also improve the solubility of the expressed protein is to attach protein domains that are known to be soluble and express well in the selected expression system (Table 2; Walls and Loughran, 2011).

Many of the alternative prokaryotic expression systems available have been developed to circumvent deficiencies in the standard *E. coli* systems. The gram-negative *Pseudomonas fluorescens* has been engineered to secrete protein to the periplasmic and extracellular space with high efficiency and is suitable for high-density fermentations (Retallack *et al.*, 2012).

Looking at gram-positive bacteria there are several expression systems that have been used for heterologous protein production with success. Many of these bacteria secrete proteins naturally with high efficiency which enables high protein production and facilitates downstream protein purification. The most commonly used species is *Bacillus subtilis*, usually variants that have been modified to lack extracellular proteases to increase the stability of the produced proteins (Pohl and Harwood, 2010). A more recent addition to the available gram-positive expression systems is *Corynebacterium glutamicum* (commercialized by Ajinomoto as CorynexTM) that can secrete both folded proteins through the twin arginine translocation (TAT) pathway and proteins that fold in the extracellular space through the secretion translocase (SEC) pathway (Kikuchi *et al.*, 2009).

There are bacterial expression systems with more specific utility for certain protein classes. One such example is

Lactococcus lactis that has been shown to be well suited to secrete proteins but also to express membrane proteins (Villatoro-Hernandez *et al.*, 2012; Kunji *et al.*, 2003). Selection is facilitated by the use of auxotrophic strains and there is an inducible variant (P170) that is activated by the accumulation of lactose during fermentation. Other benefits of the gram-positive bacteria mentioned here are that they are GRAS (Generally Regarded As Safe) and in contrast to gram-negative bacteria do not produce endotoxins. Endotoxins are lipopolysaccharides that are synthesized by gram-negative bacteria as components of the outer cell membrane and elicit an immune response when used *in vivo* in animals and humans.

Yeast Expression Systems

Yeasts are single cell microbial eukaryotes that have been used in food production by humans for thousands of years. The classic Baker's yeast, *Saccharomyces cerevisiae* was the first yeast to be used for recombinant protein production, but in the last 10 years *Pichia pastoris* has rapidly gained popularity and is a common choice today (Mattanovich *et al.*, 2012). Other yeasts that are increasingly used for heterologous protein production are *Kluyveromyces lactis* and *Pichia angusta* (formerly known as *Hansenula polymorpha*) (van Ooyen *et al.*, 2006; Gellissen *et al.*, 2005).

For the expression of heterologous protein in *S. cerevisiae* there are options for both episomal and integrative vectors. In both cases the promoters that direct expression of the gene of interest is either constitutive (usually from the glycolytic pathway) or inducible (PGAL1/PGAL10). Episomal vectors in *S. cerevisiae* make use of 2 μ , which is a 6.3 kbp plasmid that can be extrachromosomally maintained at 50–100 copies in the nucleus.

Pichia pastoris and *P. angusta* are both methylotrophic yeasts and expression systems based on the strong promoters induced by methanol have been developed for both systems (Cregg *et al.*, 2000; Gellissen *et al.*, 2005). The PAOX1 promoter for alcohol oxidase 1 in *P. pastoris* is very strong and can drive expression of heterologous proteins up to several grams per liter. Using methanol for induction has some technical safety complications since it is flammable and toxic. Other gene regulatory sequences have been adapted for use in recombinant protein production in *P. pastoris* and both inducible (PFLD; acetamide) and constitutive (PGAP) promoters are available (Cos *et al.*, 2006).

Protein expression in the methylotrophic yeasts are always driven from vectors that have been integrated into chromosomal DNA by homologous recombination. Strains which have vectors stably integrated are commonly selected through antibiotic selection with Zeocin or with *ade2* auxotrophs (commercialized by Life Technologies as *Pichia Pink*TM). Cytoplasmic proteins can be expressed successfully in *P. pastoris* although it is more frequently used to secrete proteins. Complex eukaryotic proteins with multiple disulfide bridges have been expressed in *P. pastoris*. To enable secretion the pre-pro sequence from the α -mating factor of *S. cerevisiae* is introduced at the N-terminus of the protein to be expressed. The methylotrophic yeasts are especially well suited for high-density cultivation and, in bioreactors, can reach over 120 g of dry weight per liter.

As eukaryotes, yeasts are capable of most posttranslational modifications including glycosylation. Depending on the use of the protein product, care should be taken since there are significant differences in the type of glycans added to proteins by yeast compared to mammalian cells. Glycans added to the nitrogen of asparagine in the sequence Asn-Xaa-Ser/Thr (N-glycosylation) are similar to what is seen in mammalian cells. But in yeasts the produced N-glycosylation structures are different from what is seen in mammalian cells and are very rich in mannose, an effect termed hypermannosylation. In *S. cerevisiae* these chain are much longer (50–150) than what is usually seen in *P. pastoris* (8–17). Glycosylation of the O-type on serines/threonines also occur in *P. pastoris* but is less characterized.

Besides the yeasts described above, other unicellular microbial eukaryotes used for recombinant protein production are filamentous fungi such as *Aspergillus spp.* and *Trichoderma spp.* (Ward, 2012) and protozoans including *Leishmania tarentolae* (Niimi, 2012). Their use for heterologous protein production in research laboratories has so far been limited. The interested reader can find more information about these systems in the suggested further reading.

Cell-Free Expression Systems

The cell-free expression systems are based on cell extracts that contain all the necessary macromolecular components for translation of protein from messenger RNA (mRNA). Rabbit reticulocytes and wheat germ cells are two common eukaryotic sources for extracts that have high intrinsic capacity for protein production (Bernhard and Tozawa, 2013; Whittaker, 2013). When using extracts from *E. coli* the bacteria have been cultured at very high specific growth rates which increases the ribosome concentration and hence the translation capacity of the extract. During the preparation of the extract, most low molecular weight molecules are lost and must be supplemented back to enable efficient translation; this includes amino acids, energy sources, cofactors, and energy regenerating systems.

Eukaryotic extracts are isolated from the cytoplasmic fraction and lack endogenous RNA polymerase activity. Instead exogenous RNA polymerases (from bacteriophages T7 or SP6) are normally added, and the corresponding promoter is incorporated into the DNA template. For extracts from *E. coli*, the endogenous RNA polymerase activity can be utilized but often the extract is made from strains containing the DE3 prophage and hence can express T7 RNA polymerase. The DNA used as templates in the cell-free expression systems can be added either as plasmids or linear fragments; this enables rapid screening of protein variants directly from polymerase chain reaction products.

In the first generation of cell-free expression systems all necessary components were directly mixed in the reaction chamber and the production stopped once a required component was depleted. The current methodology is based on continuous-exchange cell-free systems where fresh precursors are provided and waste products are removed across a dialysis membrane to enable much longer reaction times (Stech *et al.*, 2014).

The unique characteristic of cell-free systems is that they are fast since they are not dependent on the growth characteristics

of any biological system. It is also an open system which means that it is possible to directly add to the reaction unnatural or isotopically labeled amino acids (Ozawa *et al.*, 2012). Since the reaction is independent of the viability or growth of any cell, the expression of toxic proteins or incorporation of unnatural amino acids can be more efficient. Since most enzymatic activities from the cell are suppressed and the reaction is fast, proteins that are sensitive to proteolytic degradation can be isolated intact. Also membrane proteins are frequently expressed in cell-free systems, either directly into detergent micelles or as protein precipitates that are easily isolated and subsequently solubilized (Nozawa *et al.*, 2010). The downside of cell-free systems is that they are expensive to run at scale and have therefore been limited to mostly screening applications.

Insect Expression Systems

Moving on in complexity from the single-celled microbial expressions systems discussed earlier, we reach higher order eukaryotic expression systems. Insect cells have long been considered an obvious choice for expression of proteins that are not suitable for expression in microbial systems. These cells have some important benefits over prokaryotes in terms of expression complexity. They are able to process posttranslational modifications that may be required by heterologous recombinant proteins, including signal peptide cleavage, glycosylation, myristylation, sulfation, amidation, γ -carboxylation, and β -hydroxylation. However, whilst insect cells are capable of expressing N-linked glycoproteins, the chains formed are significantly different from those seen in mammalian cells (Jarvis *et al.*, 1998; Kim *et al.*, 2013). As shown in Table 3, insect glycosylation chains are limited to high mannose glycans or glycans with trimannosyl cores as they lack sufficient glycosyltransferases needed to process complex chains. Engineered cell lines have been developed that attempt to mimic more mammalian-like glycosylation patterns (Jarvis *et al.*, 1998). Life Technologies have licensed a humanized glycosylation cell line from GlycoBac and have commercialized it as the Mimic™ Sf9 cell line. Insect cells are naturally able to secrete extracellular proteins through the endoplasmic reticulum (ER) and Golgi apparatus. However, typical yields of recombinant proteins are usually several-fold lower than the microbial systems.

Based on data available from the Worldwide Protein Data Bank, insect cells appear to be the preferred eukaryotic

expression system (Figure 2), and second overall expression system after *E. coli*, for producing proteins for structural studies. This is at least partially due to the fact the system is amenable to fairly high-throughput expression screening. Of the immortalized insect cells available, the most commonly utilized lines are derived from *Spodoptera frugiperda* (fall armyworm) with Sf9 and Sf21 being the most common. Expression systems involving these lines usually utilize baculoviruses as the vector for delivery of recombinant genes. In addition to the *spodoptera* lines, cells derived from *Trichoplusia ni* (cabbage looper) are also used with baculoviral-mediated delivery (High Five™ BTI-TN-5B1-4 and Tn-368). These cells were originally developed and commercialized to solve a perceived failing of *spodoptera*-derived lines in expressing high levels of secreted proteins (Wickham *et al.*, 1992).

Generation of recombinant baculoviruses containing the heterologous gene of interest is commonly achieved by either *in vivo* transposition in *E. coli* or direct recombination in insect cells. The most common baculovirus isolates used for heterologous recombinant protein expression are from *Autographa californica* (alfalfa looper) multiple nuclear polyhedrosis virus (AcMNPV) and less commonly from *Bombyx mori* (silkworm) nuclear polyhedrosis virus (BmNPV). In almost all cases, the gene of interest is inserted downstream of the baculoviral polyhedrin promoter, in place of the endogenous polyhedrin gene; this gene is not required for baculoviral-mediated infection of cultured cells. If multiple heterologous genes are to be expressed from the same baculovirus, the p10 promoter is commonly used. There are many systems that have been commercialized to perform the modification of the baculoviral genome for the purpose of generating recombinant proteins, the most common are listed in Table 4. Once a high-titer virus has been established, this can be used to express recombinant proteins in addition to propagation of further virus generations.

Due to the lytic nature of the viral expression system, heterologous recombinant protein generation in these systems is relatively quick; commonly no longer than three days post infection. However, the lytic nature must also be taken into account when considering the heterologous protein of interest; intracellular proteins must be harvested before the lytic cycle has progressed too far, preventing harvesting of the whole cells, and any proteins susceptible to proteolysis require harvesting before they have been overexposed to proteases released during lysis.

As an alternative to the baculoviral-mediated methods, traditional transfection systems have been developed.

Table 3 Differences between insect and mammalian glycosylation

	Insect cells	Mammalian cells
Enzymes produced	Low levels of glycosylation enzymes required to produce complex glycoproteins	Working levels of glycosylation enzymes required to produce complex glycoproteins
Resulting glycoprotein sidechain	Paucimannose or high mannose glycan	Complex N-glycans with terminal sialic acid
Glycoprotein sidechain structure		

Note:  N-Acetylglucosamine;  Mannose;  Galactose;  Sialic acid.

Figure 2 Impact of eukaryotic expression systems on structural biology. The graph shows the number of new, unique entries added to the Protein Data Bank (PDB) per year (unique is defined here as entries with <90% sequence identity). Note that *S. frugiperda* equates to Baculovirus expression, whilst *Homo sapiens* corresponds primarily to HEK293 cells (PDB was searched using '*Homo sapiens*' as a search term for expression system, but no attempt was made to quantify the exact number of entries using HEK293 cells specifically). Reproduced with permission from Assenberg, R., Wan, P.T., Geisse, S., Mayr, L.M., 2013. Advances in recombinant protein expression for use in pharmaceutical research. *Current Opinion in Structural Biology* 23 (3), 393–402.

Traditional transient transfection of *spodoptera* cells is used in the InsectDirect™ (BD Biosciences) transfection system. Additionally, systems using Schneider 2 (S2) cells derived from *Drosophila melanogaster* (fruit fly) embryos have been developed as both transient and stable expressions systems. Unlike the viral-mediated system described above, expression of heterologous protein is achieved via traditional transfection of the cells with a suitable plasmid vector. Stable lines may be developed using antibiotic resistance markers to enable longer term expression. Inducible expression can be achieved in the S2 system by utilizing an inducible promoter, such as the metallothionein promoter which can be induced by the presence of heavy metals (usually copper or cadmium). Alternatively, constitutive expression can be achieved by using a constitutive promoter such as the actin 5C promoter (Angelichio *et al.*, 1991).

For details of transient transfection methodologies, see Section Mammalian Expression Systems.

Mammalian Expression Systems

Mammalian expression systems provide for the most comprehensive extent of posttranslational modifications. However,

this is tempered by the fact that, until recently, yields from these systems have been much lower than any of the cellular alternatives already discussed. Improvements in this area have been boosted by the fact that many biopharmaceuticals are expressed in these systems (Wurm, 2004) giving rise to a strong driver to improve yields (Durocher *et al.*, 2002; Dar-amola *et al.*, 2014). Like the insect systems described in Section Insect Expression Systems, mammalian cells are also naturally able to cleave signal peptides and secrete extracellular proteins.

Delivery of recombinant genes into mammalian cells has traditionally been achieved through transfection of the cells with plasmid DNA (Figure 3), either through binding of the DNA to a suitable transfer molecule or electroporation. There are a variety of transfer molecules available to traffic DNA across the cell membrane to which it is naturally impermeable, and the most commonly used for recombinant protein expression are summarized in Table 5. Additional methods include the use of viral delivery systems, including lentivirus and a modified baculovirus system (BacMam). In all cases the vectors utilize a promoter suitable for over-expression in mammalian cells, often a constitutive viral promoter such as the cytomegalovirus (CMV) immediate early promoter.

Table 4 Common commercially available baculovirus expression systems

Baculoviral-mediated expression system	Notes
Bac-to-Bac™; Life Technologies (ThermoFisher)	Heterologous gene insertion achieved via <i>in vivo</i> transposition in DH10Bac™ <i>E. coli</i> . Purification of bacmid DNA via alkali lysis and subsequent transfection of insect cells yields budding virus particles
MultiBac™; Geneva Biotech	Specifically designed to allow for multiple heterologous genes to be expressed from a single viral genome. Heterologous gene insertion achieved via <i>in vivo</i> transposition in DH10MultiBac™ <i>urbo</i> or EmBacY <i>E. coli</i> . These strains contain bacmids with <i>v-cath</i> and <i>chiA</i> knockouts. Purification of Bacmid DNA via alkali lysis and subsequent transfection of insect cells yields budding virus particles
BacMagic™; Merck Millipore	Heterologous gene insertion achieved via <i>in vivo</i> recombination in insect cells. BacMagic1 is a <i>chiA</i> knockout, BacMagic2 is a <i>chiA</i> and <i>v-cath</i> knockout, whilst Bacmagic3 is a <i>chiA</i> , <i>v-cath</i> , p10, p24, and p26 knockout. Transfection of insect cells with a viral genome in addition to the appropriate donor vector leads to direct production of budding virus particles
BaculoGold™; BD Biosciences	Heterologous gene insertion achieved via <i>in vivo</i> recombination in insect cells. Transfection of insect cells with the viral genome in addition to the appropriate donor vector leads to direct production of budding virus particles
FlashBAC™; Oxford Expression Technologies	Heterologous gene insertion achieved via <i>in vivo</i> recombination in insect cells. FlashBACGOLD is a <i>chiA</i> and <i>v-cath</i> knockout. FlashBACULTRA is a <i>chiA</i> , <i>v-cath</i> , p10, p24, and p26 knockout. Transfection of insect cells with a viral genome in addition to the appropriate donor vector leads to direct production of budding virus particles
BaculoDirect™; Life Technologies (ThermoFisher)	Heterologous gene insertion achieved via <i>in vitro</i> recombination. Subsequent transfection of insect cells yields budding virus particles

Note: Table shows the major baculoviral-mediated expression systems available, including notes on the individual features of each.

The most commonly used mammalian expression cell lines are derived from *Homo sapiens* (human) and rodent species, notably *Cricetulus griseus* (Chinese hamster) and *Mus musculus* (house mouse). The most well-known mammalian expression line is the human-derived HEK293 cell. Developed in 1973 by transformation of an embryonic kidney culture with sheared adenovirus DNA, it became popular due to the ease at which it is cultivated and transfected by many of the traditional transfection methods. Increasingly, systems based on Chinese hamster ovary lines (CHO K1 or CHO DG44) are becoming more popular. These lines have traditionally been more difficult to transfect, but are able to reach higher cell densities than standard HEK293 cells and are amenable to a variety of cell culture manipulations, including hypothermic shift and treatment with histone deacetylase inhibitors, that contribute to higher protein yields (Wulhfard *et al.*, 2010). More recently, efforts have been made to derive new mammalian expression hosts, from novel progenitor cell lines. For instance, the CAP systems from CEVEC Pharmaceuticals use human amniocyte-derived cells from excess cells obtained during amniocentesis.

The simplest mammalian expression systems involve introducing plasmid DNA to the cells and allowing the cells to produce protein (Figure 4) until the plasmid is naturally lost. These systems are known as transient methodologies due to the limited expression window. As mentioned previously, plasmids are self-replicating, extrachromosomal, closed circular DNA fragments. Although plasmids can be replicated in mammalian cells, they are not automatically maintained with chromosomal DNA during cell division. This means that as the cells divide they are prone to lose the plasmid DNA as it requires re-trafficking to the nucleus. Since this results in a fairly short period of expression, usually peaking between 24 h and 72 h, several approaches have been used to extend the expression window with the intent of improving the recombinant protein expression yield.

The most obvious way to improve the expression window is to integrate the heterologous gene into the host cell's chromosomal DNA. At this point you are generating a stable cell line that will continue to express the protein of interest so long as the heterologous gene remains in a section of open chromatin accessible to RNA polymerase. The downside to this approach is that it usually takes a significant amount of upstream effort to prepare the cell line prior to expression of your heterologous protein. Generation of a stable cell line for expression can be carried out via a variety of methods, including viral delivery and linearized plasmid delivery, though the end result is essentially the same; incorporation of the heterologous gene along with a selective marker that can be used to enrich for your integrants.

Since stable cell-line generation is a lengthy process, much effort has continued into improving transient methodologies for research purposes. There have been four main areas of focus to this end: improve transfection efficiency to ensure a greater population of expressing cells, improve the productivity of your cells, improve the window of expression, and improve the density of your culture to increase the volumetric yield.

As described in Table 5, there are a number of commercially available reagents that have been designed and optimized to efficiently transport DNA across the cell membrane. Factorial experimental design approaches are routinely used to determine the conditions for which maximal transfection efficiency can be achieved by these reagents. However, often these reagents suffer from inherent toxicity issues and efforts have been made to investigate alternative delivery systems. The large-scale electroporation devices from MaxCyte®, such as the MaxCyte STX®, have been shown to provide for excellent transfection efficiencies and reports suggest this method can be used for recombinant protein generation. Additionally, BacMam has been successfully used for recombinant protein

Figure 3 Schematic of a plasmid used as a vector for recombinant protein expression in mammalian cells. (a) The plasmid contains elements to enable episomal replication or stable cell-line generation. The EBNA-1 gene provides EBNA-1 protein to enable episomal replication of the plasmid via the *oriP* sequence. For stable cell-line generation, the plasmid contains a gene conferring resistance to hygromycin B. For selection in an *E. coli* propagation strain the plasmid contains the *bla* gene encoding beta-lactamase providing resistance to ampicillin. Also depicted is the position of the origin of replication (ColE1 pUC) and the expression cassette. (b) Contents of the expression cassette. The CMV enhancer and promoter region are required for initiation of transcription in mammalian cells. The Kozak sequence exists adjacent to the start codon (ATG) and assists in initiation of translation. The heterologous gene of interest lies in the protein coding sequence between the start and stop codons. After the gene comes the polyadenylation signal which codes for the mRNA poly(A) tail. The poly(A) tail is required for the nuclear export, translation, and stability of the transcript.

expression in mammalian cells (Ames *et al.*, 2007). BacMam uses the same baculoviral-mediated technology described in Section Insect Expression Systems and is a modification of the AcMNPV baculoviral isolate. Baculoviruses do not infect or replicate in mammalian cells, however, it was discovered that they are able to traffic their genetic content into mammalian cells under normal cell culture conditions via a method termed 'transduction.' By utilizing an appropriate mammalian-effective promoter in place of the polyhedrin promoter it is possible to generate virus particles that act as heterologous gene delivery vehicles into mammalian cells.

To improve the productivity of the cells, media, supplements, and nutrient feeds have been continually revised and optimized. There are a number of commercially available feed products that have been designed to boost expression yields by providing a variety of nutrients and energy sources, the most common of which are noted in Table 6. Additionally, work has focused on molecules that may affect cell biology in such a way as to boost expression levels. Aliphatic acid-type histone deacetylase inhibitors, such as butyric and valproic

acids, have been added to cultures as expression enhancers (Wulhfard *et al.*, 2010). The mechanism by which these molecules confer their performance-enhancing effect is not fully understood, but by preventing deacetylation of histones the molecules prevent the condensing of chromatin structures, thus keeping DNA more accessible. It is unclear, however, why this activity should confer enhancement to non-chromosomally located heterologous genes. Life Technologies' Expi293™ expression system makes use of proprietary enhancer supplements added post transfection to improve productivity.

Improving the expression window can be achieved by ensuring the plasmid containing the heterologous gene is maintained during cell division. Episomal expression systems have been developed and commercialized for this purpose. These systems make use of the machinery used by viruses in latent phases of their cycle. By including a viral origin and DNA-binding sequence on the expression plasmid and a source of the appropriate DNA-binding protein, for example the *oriP* origin and repeat binding sequence and EBNA-1 protein from

Table 5 Common transfection reagents for recombinant protein expression

Transfection reagent	Type	Notes
Calcium phosphate (usually as calcium chloride and HEPES buffered saline)	Salt precipitant	Co-precipitates of DNA and calcium phosphate are able to bind to the cell surface and enter via endocytosis. It is an extremely low-cost method, but very cell type dependent and time consuming to perform at scale
Polyethylenimine (PEI)	Cationic polymer	PEI condenses DNA into particles that can bind to the cell surface. Again DNA entry is via endocytosis. PEI is very low cost and therefore economical at scale. However, it is also extremely cytotoxic
JetPEI®; Polyplus transfection	Cationic polymer	Commercial, linear PEI derivative transfection reagent
Freestyle™MAX; Life Technologies (ThermoFisher)	Proprietary	Commercial reagent used in the Freestyle™ expression system. The system comprises transfection reagent, optimized media, and cell lines derived from HEK293 or CHO
Expiectamine™293; Life Technologies (ThermoFisher)	Proprietary	Commercial reagent used in the Expi293™ expression system. The system comprises transfection reagent, transfection enhancers, optimized media, and a cell line derived from HEK293F

Note: Table shows commonly utilized transfection reagents for recombinant protein expression from mammalian cell lines.

Figure 4 Diagram demonstrating transfection reagent-mediated plasmid DNA delivery and subsequent transgene expression. Figure illustrates (A) transfection complex formation, (B) DNA uptake, (C) DNA trafficking, (D) transcription, and (E) translation of recombinant protein.

Epstein Barr virus, the plasmid can be coupled to chromosomal DNA during cell division. This process greatly improves the retention of the plasmid DNA, which in turn significantly

improves the expression window. Stable cell lines expressing the EBNA-1 gene, or variants thereof, have been developed specifically for use with *oriP*-containing plasmids. The most

Table 6 Common commercially available media supplements for recombinant protein expression

Media supplement	Notes
BD Recharge™; BD Biosciences	Chemically defined supplement designed to mimic yeast peptones by supplying only the key nutrients
BD Resurge™; BD Biosciences	Family of five chemically defined feed supplements. Containing a proprietary mix of nutrients
CD EfficientFeed™; Life Technologies (ThermoFisher)	Family of chemically defined feed supplements in various formats. They contain a proprietary mix of nutrients including energy source, amino acids, and vitamins
HyClone Cell Boost; GE Healthcare	Family of six chemically defined feeds in increasing complexity. They contain a proprietary mix of nutrients starting with glucose and amino acids, through to lipids and growth factors
HyPep 1510; Kerry	Ultrafiltered soy hydrolysate containing amino acids and peptides
Tryptone N1; Organotechnie	Casein hydrolysate containing amino acids and peptides
Tryptone Plus; Organotechnie	Casein hydrolysate containing amino acids and peptides
Yeast extract	Prepared by autolysis of <i>S. cerevisiae</i> cultures, it is a rich, though unrefined, source of amino acids and peptides

Note: Table shows common media supplements designed to boost expression levels in mammalian expression systems.

common EBNA-1 lines are based on HEK293 cells, but CHO variants are also available. Taking this further, it is possible to supply selection pressures to cells with episomally replicating plasmids to ensure retention. This concept has been developed and commercialized by Icosagen in the QMCF system.

Recently, Life Technologies have been specifically looking at increasing the cell culture densities that can be achieved during transient expression. They have commercialized a HEK293-based system (Expi293™) that allows for high-density transfection and high-density production. By increasing the number of cells per liter, the amount of protein produced per liter of culture is increased proportionally. The system includes a HEK293 clone that showed excellent growth and heterologous expression properties, along with a new chemically defined media to support the higher densities.

Summary/Conclusion

The range of available expression systems have grown significantly over the past 15 years. Technical development and reduction in the complexity of setup required for performing work in the more complex systems, especially those based on mammalian cells, have increased their use even in less specialized laboratories. Today the choice of expression system has increasingly become a decision based on what is most appropriate for the protein to be expressed rather than availability of equipment and technical competence.

It is challenging to make general recommendations on the suitability of different expression systems. As has been described in the sections above the ability to express complex proteins with posttranslational modifications increases from the microbial to the eukaryotic systems, especially the mammalian systems. Looking at historical use most often *E. coli* is utilized for the expression of relatively small intracellular proteins not requiring disulfides or posttranslational modifications. Many of the gram-positive bacteria are used for secreted proteins and membrane proteins. The more advanced eukaryotic systems (insect and mammalian) are more all-purpose systems that can be very versatile. But an analysis of the most appropriate expression system for a given protein should be based on the characteristics of the expressed protein and the subsequent application (Brondyk, 2009).

Affinity chromatography Separation based on a biological affinity for a specific molecule such as an antibody, a sugar, or other bound moiety.

Anion exchange The exchange of one anion for another electrostatically bound to a cation immobilized on a matrix.

Cation exchange The exchange of one cation for another electrostatically bound to an anion immobilized on a matrix.

Chromatography A method used for the separation of mixtures of molecules that relies on the differential partitioning of molecules between phases. In column chromatography, the partitioning takes place between a solid, stationary phase and a mobile, liquid phase.

Density gradient centrifugation A centrifugal method where particles are separated in a preformed density gradient by the application of centrifugal force until they reach a zone equal to their own density.

Dialysis The process of separating molecules in solution by differences in their diffusion through a semipermeable membrane. Often used to remove or exchange salts from protein solutions.

Differential centrifugation A centrifugal method where larger particles are separated from smaller particles by subsequent increases in centrifugal force.

Electrophoresis A method of separating charged molecules based on their migration in an electrical field.

Isoelectric focusing An electrophoretic technique where a molecule will move in a pH gradient generated by an electric field to a pH equivalent to its isoelectric point.

Isoelectric point (pI) The pH of a solution at which the net charge on a molecule is zero, i.e., the sum of the positive charges is equal to the sum of the negative charges. At pH above the pI, the protein will be negatively charged. At pH below the pI, it will be positively charged.

Isotachopheresis An electrophoretic method where charged molecules are focused at the interface between two electrolytes with different mobility in an electric field.

Ligand A substance, usually a small molecule that forms a complex with a biomolecule, usually a larger molecule such as a protein.

Matrix A substance such as a chromatography gel within which something develops or is contained.

Membrane filtration A method to separate substances by passing them through a membrane with a fixed pore size that lets some pass through and retains others.

Organelles Subcellular structures including the mitochondria, nucleus, endoplasmic reticulum, golgi bodies, endosomes, lysosomes, phagosomes, synaptic vesicles, chloroplasts, and others that contain molecules and other structures separated from the cytoplasm by a membrane.

Polymerase chain reaction An automated, cyclic enzymatic method for the *in vitro* amplification of DNA molecules.

Recombinant DNA technology The isolation, manipulation, and study of single genes.

Sodium dodecyl sulfate-poly-acrylamide gel electrophoresis (SDS-PAGE) An electrophoretic technique for the separation of proteins based on their size in an insoluble polyacrylamide gel. Since the proteins are denatured and dissociated by the SDS, they migrate through the gel based on their covalent molecular weights.

Sonication Application of sound energy to agitate particles. In the context of protein isolation it is used for the disruption of structures such as cells by exposure to ultrasonic frequencies.

Ultrafiltration A form of membrane filtration where a solution is forced through a membrane by centrifugation or applying pressure.

Western blot Electrophoretic separation followed by detection of the protein with a labeled, specific antibody to the desired protein.

Introduction

Proteins normally exist *in vivo* and perform their function in a dense mixture of other proteins, carbohydrates, lipids, nucleic acids, salts, and other metabolites. They may exist free in solution, as components of protein complexes, adsorbed to cellular structures, or as integral parts of cellular components such as membranes. In all cases, they exist to perform a function. In order to be able to assign a particular function to a particular protein, it is usually necessary to isolate it so that it can be studied in the absence of other proteins. In isolation, their physical and chemical characteristics, and in the case of

enzymes their catalytic properties, can be determined so that one is reasonably sure that a particular function is being performed by a specific protein, or in some cases, a defined group of proteins.

Scientists have been engaged in the endeavor of protein isolation since it was first realized that proteins and enzymes were individual molecular entities that could be differentiated from their environment. Indeed, most of what we know about the function of individual proteins comes from studies of isolated homogeneous protein samples. It could be argued that not all proteins may act the same in isolation as they do in their native milieu, but at the very least, studying them in

isolation provides a detailed and invaluable starting point upon which to base further investigations and is really still the best way to pin down a particular protein's function.

Literally thousands of articles have been published that either deal with the isolation of a particular protein or contain sections that deal with it. The thing that one will note when reading a large number of these articles is that they often appear to be quite similar but hardly ever exactly the same. The protocols may look similar because there are a limited number of techniques from which to choose, but different because, while some techniques may be successful with many different proteins, they will not be effective for all proteins. If the same steps are used, the order in which they are performed may differ. The art of protein isolation comes in knowing what techniques are available and how to most efficiently apply them to the particular protein at hand. This article will hopefully assist in the former, but the latter comes with experience. With some exceptions, almost all published protocols for protein isolation did not work the first time and came from trial and error, with incremental successes and failures along the way.

The goal is to obtain an essentially homogeneous or 'pure' protein in sufficient quantity to produce the desired information. A purification protocol cannot be considered truly successful if there is not sufficient protein at the end of it to perform the required analyses. Two things to strive for in this regard are to find conditions where the protein is stable and to minimize losses by minimizing the number of steps in the procedure because each step comes with unavoidable loss of material.

Before the advent of gene cloning and the polymerase chain reaction (PCR), virtually all protein isolation started with a tissue or a culture of microorganisms followed by a multistep purification procedure. One of the great advances in protein isolation came with recombinant technology and the ability to over-express a particular protein. Recombinant technology also allowed the protein to be expressed with a 'tag' that could be used to pick it out of solution with a matrix that contained an entity with specific affinity for the tag. Such a technique is used very often today, but not all proteins can be successfully over-expressed so it is still quite necessary to be familiar with more 'conventional' isolation techniques. In addition, various isolation techniques can be used to 'clean up' protein preparations that are not rendered pure enough by the affinity tag technique. In all cases, their success relies on differences in the location, solubility, charge, size, and affinity of each protein.

This article will focus on laboratory-scale isolation. That is, procedures that can be used in a typical academic laboratory setting to produce modest amounts of protein for analytical purposes rather than large scale production processes. Although many of the same techniques are used in both settings, the scale of production-based isolation is such that many new challenges arise and the infrastructure required is very different.

A protein isolation procedure can be viewed as a combination of steps where the protein progresses in purity with each step: (1) identification and acquisition of a source, (2) extraction from the source, (3) separation from nonprotein components such as nucleic acids and lipids, (4) concentration

of the bulk protein and separation into fractions that contain different proteins, and (5) fine-resolution techniques such as chromatography (Figure 1) that provide the final product.

A few words about purity are in order. What does 'pure' mean and how do you know that a protein is pure? Conceptually, 'pure' means that no other component is present. Of course, this excludes things like buffer components that are intentionally included. For proteins, it usually means the presence of other proteins, but it could also mean the absence of other things like nucleic acids, carbohydrates or lipids that are not covalently attached to the protein. In reality, true purity is not often completely achievable or measurable. The best that you can do is to demonstrate that you are not able to detect the presence of other components or that they are present at less than a certain acceptable percentage. This depends on the sensitivity of the method that you use for detection and the type of component that method will detect.

Unfortunately, an article of this size does not allow an in-depth discussion of every aspect of protein isolation. Hopefully, this article will provide an overview of what is available for the task at hand and provide references where more detailed information can be found. There are many excellent reference sources dealing with protein isolation that anyone wanting to learn more about the subject will find very valuable. Notable among them are the *Methods in Enzymology* series and *Current Protocols in Protein Science*. These and others are listed in the Further Reading section.

The Protein Source

How a particular purification is designed and carried out is very dependent on the source of the protein. It used to be that the only source was from an animal or plant tissue or cultures of cells or microorganisms. More than likely, the protein of interest was not present at levels any higher than many other proteins and often less, thus requiring a significant enrichment along the way. With over-expressed proteins in recombinant systems, the protein of interest is already enriched since it is usually present at levels much higher than any other protein.

One potential drawback from over-expression of a protein from one species in another species, such as a protein from a eukaryote expressed in bacteria, is the formation of inclusion bodies. These are inactive, insoluble aggregates of protein formed when the expressed protein finds itself in a foreign environment at a very high concentration. In addition, mechanisms for such things as glycosylation, membrane transport, and specific protein folding are not generally found in prokaryotes so that the resultant protein may take up a nonnative conformation. One potential advantage of a protein forming inclusion bodies is that, if it can be reactivated from the aggregated form, the inclusion bodies themselves can serve as a form of purification (Palmer and Winfield, 2004; Winfield *et al.*, 2004; Singh and Panda, 2005). The formation of inclusion bodies may also be temperature sensitive. In many instances, failure to obtain soluble protein after expression in *Escherichia coli* at 37 °C, for example, can be at least partially overcome by expressing the protein at lower temperatures, such as 16 °C. While substantial amounts of protein may still

Figure 1 An example of a column chromatogram. A heterogeneous protein mixture was applied to an ion-exchange column and developed with an increasing salt gradient. Absorbance (bold solid line) and enzyme activity (•) are plotted versus the fraction number of the collected column eluate. The diagonal line indicates the gradient of increasing salt concentration. Pooling of fractions 63–75, for example, will yield a more pure protein than that applied to the column.

be found in the insoluble pellet, the supernatant may often contain sufficient amounts of active protein.

Obviously, one of the biggest purification steps one can make is to start with an organ or other tissue rather than the whole organism. But, which tissue to use can be just as important since enzymes can be differentially expressed depending on the tissue. For instance, a particular enzyme may be present in high amounts in the kidney but not in the liver. Therefore, although one may be able to isolate it from the liver, isolating it from the kidney may be easier because there is a lot more to start with and yield will be less of a concern. However, tissues can express specific isoforms differentially so this also should be taken into account when choosing a source.

Assays

Equally important as a good source of protein is a good assay for the protein of interest. It is usually not possible to purify a protein if you cannot identify or locate it as you proceed to separate it from other material. If it does not have enzymatic activity or there is no enzymatic assay available, it could be followed by western blotting or perhaps even simply by following a particular band on a sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) gel. In the case of western blotting, it is possible to make antibodies to a protein without having it in pure form first if the sequence is known

from genome studies. This is done by making antibodies to synthetic peptides of hydrophilic stretches of amino acid sequence found in the target protein (Grant, 2002). But remember, you usually isolate what you assay for. If, for instance, your assay detects more than one protein because of cross reactivity, your end product may be different than intended or possibly a mixture of things.

As a protein purification proceeds, one is also interested in determining the total of all protein present in a fraction as a way to judge the efficacy of each step. There are many ways to assay for the total amount of protein, from something as simple as reading the absorbance of a solution (Grimsley and Pace, 2003) to chemical-based colorimetric assays (Olson and Markwell, 2007) and even quantitative amino acid analysis (Rutherford and Dunn, 2011).

Considerations

Accountability

The goal in protein purification is to remove other material from the fraction containing your target protein while retaining as much of your target protein as possible. A good way to monitor this is by constructing a protein purification table that records the specific activity and yield at each step (Table 1). The specific activity of your protein is simply some assessment of the level of your protein relative to all the

Table 1 Example of a protein purification table that documents the work-flow of a purification protocol. The final protein solution provided 15 mg of protein and represented a purification of over 3600 fold with a yield of 36%

Step	Total activity (units)	Total protein (mg)	Specific activity (units/mg)	Yield (% activity)	Purification (fold)
Homogenate/10 000 × g supernatant	50 000	150 000	0.33	100	1.0
40–60 % Ammonium sulfate fraction	40 500	90 000	0.45	81	1.4
Blue-sepharose	36 000	10 000	3.6	72	10.9
QAE-sepharose	20 000	100	200.0	40	606
Size exclusion-sepharose	18 000	15	1200.0	36	3636

protein in the sample. It may be expressed in terms of milligrams of target protein per gram or milligram of total protein or as units of activity per milligram of total protein. Another very useful method of following a purification procedure is to run an SDS-PAGE gel of your protein sample at each step of the purification. The goal is to arrive at a high and constant specific activity and a single band on an SDS gel (or the appropriate multiple bands if your protein is composed of different subunits). If your protein does not have a measurable activity, then a combination of western blots and protein stained SDS gels may suffice to monitor the progress. The key is that you must have some way to identify the target protein. One thing to keep in mind is that although the overall goal is to continually increase the specific activity of the target protein, sometimes a productive step can also be one in which the specific activity does not significantly increase by a large amount, but a contaminant is removed that may have been difficult to remove otherwise.

Accessibility

Once a source has been identified the next step is making the protein accessible. If it is not already soluble in a biological fluid such as blood, this usually involves breaking open the tissue or cell in which it is contained in a way that does not harm the protein. Many methods have been developed for this such as mechanical disruption, freeze-thawing, sonication, high pressure, enzymatic digestion of cell walls, and treatment with detergents (see Further Reading: Scopes, *Methods in Enzymology*). Detergents can be particularly useful for membrane or lipid-associated proteins that are not normally soluble in aqueous solution but they can also interfere with some techniques (Arnold and Linke, 2008; Coligan, 1998).

Stabilization

Once a tissue or cell is broke open, the protein is also subject to the outside environment and all of the elements of the tissue or cell that may have been compartmentalized and originally hidden from the protein. A successful isolation depends on the protein being stable long enough to be purified and studied. This can depend on finding the proper temperature, pH, and ionic strength in which to work. A reducing agent such as dithiothreitol (DTT) can be included if the protein is sensitive to redox conditions. If it is sensitive to

oxygen, an anaerobic chamber may be necessary. A metal chelator, such as EDTA, can be added to bind metal ions that may be detrimental or that promote proteolysis. Control of pH is critical for two reasons. First, since they contain ionizable groups, proteins have a range of pH over which they are stable or active. Note also, that the pH at which a protein is most stable may not be the pH at which it exhibits optimal activity. Secondly, most isolation procedures are sensitive to pH. So control of pH is critical to the reproducibility of an isolation procedure. There are many suitable buffers available to control pH (Blanchard, 1984; Good *et al.*, 1966). Also, proteins may need to be protected from proteases that were also liberated during cell disruption, in which case protease inhibitors may need to be added at least in the initial stages of purification. It is common practice to perform purification steps on ice or in a cold room since the reduced temperature may also serve to reduce any proteolytic damage or chemical reaction rates such as oxidation. However, unless the target protein is not stable at room temperature, most purification steps can be performed at ambient room temperature. In fact this can be an advantage because the equilibration needed for many techniques will occur faster and the operator will be more comfortable. The addition of certain substances, such as glycerol (10–30%) and sugar solutions, has also been shown to aid in the stabilization of proteins. Many proteins can be stabilized by freezing in solution or by lyophilization (freeze-drying). On the other hand, some proteins are irreversibly denatured by freezing. Storage as an ammonium sulfate precipitate can be very effective for stabilization (see below).

Repeatability

Unless you intend to never purify a particular protein again, an absolutely necessary criterion of a protein purification protocol is that it is repeatable. This requires that very good notes as to the conditions and processes of every step be kept so that each step can be reconstructed in the same way each time it is attempted. A purification protocol should be repeated at least two or three times with comparable results before it is published.

Initial Steps

Certain techniques can be very advantageous in the early stages of a purification protocol and some will be used repeatedly

throughout the purification. Differential precipitation and batch adsorption can often remove large amounts of material early on that may interfere with or overload more highly resolving techniques such as column chromatography steps.

Differential Precipitation

The inclusion of a differential precipitation step or steps relatively early in the process should always be considered because it can provide an effective and easy bulk separation, and it can also be used to concentrate the protein for subsequent steps. Since not every protein has the same characteristics, their differences can be exploited by altering their solubility by changing ionic strength, pH, or temperature, or by the addition of miscible organic solvents. Perhaps the most used and effective differential precipitation technique is ammonium sulfate precipitation. Proteins in general undergo what has been termed 'salting in' and 'salting out.' Some proteins such as globulins are insoluble at very low ionic strength and need increasing salt concentration to remain in solution. As the salt concentration increases, other proteins may precipitate. The most effective salt for this purpose is ammonium sulfate because it can effectively alter the solubility without harming the protein. In fact, ammonium sulfate is often very effective in stabilizing proteins and can be a good way to preserve a protein overnight between purification steps. The process involves adding ammonium sulfate in steps to incrementally increase its concentration. The precipitate that results is then removed by centrifugation after each addition. The choice of which concentrations to use is a matter of trial and error but a good initial concentration is 25% saturation since this is effective in removing pre-aggregated material and very high molecular weight protein. Increasing salt concentration beyond this in steps can differentially precipitate specific proteins. If the next step in the purification is sensitive to ionic strength, the salt can conveniently be removed by dialysis or ultrafiltration. Ammonium sulfate concentrations can be expressed as molar concentrations but are more often expressed as percent saturation. Since the volume of the solution will increase with added salt, the amount needed for a particular saturation is usually read from a table (Wingfield, 1998), but can also be calculated with the following equation to take the solution from an initial percent saturation level (S1) to the next percent saturation level (S2):

$$\begin{aligned} &\text{grams of ammonium sulfate to add/liter at } 20^{\circ}\text{C} \\ &= (533[S2 - S1]) / (100 - 0.3[S2]) \end{aligned}$$

Substances with specific adsorption characteristics or affinities can also be added to precipitate components such as nucleic acids. Streptomycin sulfate or polyethyleneimine (polymyxin P) are most commonly used for this purpose and recommended as one of the first steps after tissue or cell disruption (Burgess, 1991).

Batch Adsorption

The principle of this technique is similar to many of the types of adsorptive chromatography presented later and can be performed with the same types of materials, i.e., ion-exchange

gels, dye-ligand gels. The batch procedure can be performed relatively quickly compared to a chromatographic step. It simply entails mixing the protein solution in a beaker with the matrix, gently stirring or shaking for a period of time, removing the solid material by filtration or centrifugation, and either retaining the supernatant or eluting the protein from the matrix. Because it can be performed quickly and can be easily scaled up, it is particularly useful during the early stages of a purification procedure.

Centrifugation

This is one of the easiest and handiest tools available. A very early step in almost any isolation is separating particulate matter such as cellular debris from soluble components. It is also useful in separating precipitates from solution after differential precipitation procedures (see below). It can also be very useful in separating and enriching sub-cellular organelles or large protein complexes by differential centrifugation or density gradient centrifugation (Castle, 2004; Aniento and Gruenberg, 2003). It is also used to force liquid through a membrane for ultrafiltration.

Concentration

It is almost always desirable to work with smaller volumes of more concentrated material than the other way around. Since many separation techniques tend to produce fractions that are more dilute than the starting material, it is often desirable to include a concentration step before or between separation steps. A very good way to do this is to use ammonium sulfate precipitation. If the desire is simply to precipitate your protein rather than effect an additional purification, and depending on the protein's solubility, an ammonium sulfate concentration of 75–80% can be routinely employed.

Another very effective concentration technique is termed ultrafiltration. Centrifugation is used to force liquid through a membrane that will retain material above a particular size or molecular weight cut-off. Many such products are commercially available as disposable cartridges.

It is also possible to concentrate a protein by adsorbing it batch-wise to a solid matrix, such as an ion-exchange resin, and then eluting it with a small volume of buffer of sufficient ionic strength.

Chromatography

Chromatography consists of a set of techniques used to separate mixtures based on the partitioning of components between two phases. Of the different types of chromatography (i.e., Paper, Thin-layer, Column, etc.), the one most useful for protein purification is column chromatography. It consists of a solid matrix placed in a cylindrical column through which a liquid solution is passed. The differential interaction of the components in solution with the matrix results in a separation. Chromatography columns are developed by introducing liquid to the top of the column and collecting it from the bottom of the column. Collection is usually done in small

increments or volumes, called fractions, so that the separation of material accomplished by the column is retained. The fractions are then assayed individually for the presence of the target protein. The results of a chromatography can be represented by constructing a chromatogram, which is a plot of the amount of material exiting the column as a function of volume, time, or fraction (see [Figure 1](#)). Typically, total protein is measured by recording its absorbance, usually at 220 or 280 nm, and the target protein by its particular assay.

Column chromatography is very well suited for protein isolation because the conditions under which the separation occurs are usually very gentle to the protein and the resolution can be very high. Separation of protein by column chromatography relies on various chemical and physical principles and includes separations based on charge, size, selective adsorption, hydrophobic interaction, and specific affinity for certain molecules.

Ion-Exchange Chromatography

Ion-exchange chromatography (IEX) depends on the interaction of charge on the surface of a protein with an opposite charge on an insoluble matrix. Since the charge on the protein, and usually the matrix as well, is dependent on protonatable groups (amino acid side chains on the protein), the interaction between the two will depend on pH. Since most proteins do not tolerate extremes of pH, ion exchange is usually conducted at pH between 4 and 9. Most ion-exchange resins have a rather sharp transition between being charged and not, so the behavior of the chromatography is usually more sensitive to the ionization state of the protein. In a typical ion-exchange procedure, protein is loaded onto the column in a buffer that maintains a steady pH and contains a relatively low level of salt such as NaCl. Some salt is beneficial to keep the protein soluble but should be low enough so that it does not interfere with the ionic interaction between protein and matrix. Monovalent salts such as NaCl, KCl, or NH_4Cl are typically used and a typical buffer may be 20 mM Tris-HCl, pH 8.0, 100 mM NaCl. Common buffers may be Tris-HCl, ammonium bicarbonate, phosphate, or a series of buffers called the 'Good' buffers ([Good et al., 1966](#)). To maintain buffering capacity, the pH used should be within 0.5 pH units of the pK_a of the buffer. Proteins are usually eluted from the column by increasing the ionic strength of the buffer by increasing the salt concentration. This can be done in an incremental step-wise fashion but is more often accomplished with a gradient that gradually and smoothly increases the salt concentration. A typical gradient may be from 0.1 to 1 M salt. Elution from the column can also be accomplished by changing the pH of the buffer but this is not as common and usually does not provide as good of a resolution of components.

The most common charge groups on ion-exchange matrices are diethylaminoethyl (DEAE) and quaternary aminoethyl (QAE) for anion exchangers and carboxymethyl (CM) and sulfoethyl (SE) for cation exchangers. Phosphocellulose, whose phosphate group is another charged group, can be used effectively with proteins. In fact, this material can also exhibit characteristics of affinity chromatography (see below) for

proteins that bind phosphorylated compounds. The matrices themselves must also be made from materials that have pores large enough for proteins to enter. This increases the surface area accessible to proteins and thus the capacity of the matrix. Ion-exchange matrices such as Dowex, used for small molecules, are not suitable for proteins since they have very small pores and thus very low capacity for large molecules. The typical types of materials used for protein ion-exchange matrices are cellulose, agarose (Sephacrose), dextran (Sephadex), and acrylamide (Sephacryl). Other support material and ionic groups may be available depending on the manufacturer.

Determining which ion-exchange matrix to use is often accomplished by trial and error. The isoelectric point (pI) of a protein can be estimated from its amino acid composition if it is available using the protparam tool at the ExPASy website. This gives some guidance as to a starting point but the real pI may be altered by the protein structure. One general approach is to start with an anion exchange matrix like DEAE in 20 mM Tris buffer, pH 7.5–8.0, 100 mM NaCl. The pH and ionic strength of the protein solution should be matched to the column buffer by prior dialysis. The volume of sample applied to the column can be decreased by a concentration step, but a very high protein concentration should be avoided. It is actually better to load the column with a more dilute solution ($> 5\text{--}10$ mg protein/ml) to avoid local concentration and pH effects that may interfere with adsorption to the matrix. If the target protein does not 'stick' to the column, it will probably be retained by a matrix of the opposite charge. If the protein is not retained by either matrix, try adjusting the pH or lowering the salt concentration. Do not overlook the fact that just because the target protein isn't retained, it does not mean the column is not effective. Many other proteins may be retained and a good purification may have been achieved. In the end, the effectiveness is always judged by the yield and specific activity. Some proteins may be irreversibly adsorbed or even inactivated by the column matrix. In which case, the choice of matrix should be reconsidered. Always be mindful of any other buffer components. For instance, a high concentration of EDTA (a polyanionic reagent) may interfere with protein capacity on an anion-exchange resin.

The dimensions of the column are not as important for ion-exchange as they are for size exclusion chromatography where column length is a factor (see below). The major concern is for capacity and a good choice would be to use a column whose length is 4–5 times its diameter and whose diameter is large enough so that the protein adsorbs to the top 20–30% of the column matrix. In general, the wider the column the higher the flow rate that can be achieved. A higher flow rate will allow the protein to spend the least amount of time on the column and for the chromatography to be accomplished in a shorter amount of time.

Remember that when the protein is eluted from the ion-exchange column, it will be in a certain concentration of salt. If the next step is adversely affected by the salt, it must first be removed by a procedure such as dialysis or membrane filtration. As you will see next, size exclusion chromatography is also a good way to remove salt from a protein solution, and one often sees this as a step immediately following ion-exchange without prior removal of salt.

Size Exclusion Chromatography

Size exclusion chromatography has also been called gel filtration chromatography, gel permeation chromatography, and molecular sieve chromatography. This type of chromatography separates on the basis of size or more correctly hydrodynamic volume. It employs a gel matrix with pores of a specific size range and separates on the basis of whether or not a protein of a particular size can enter the pore or is excluded from the pore. Larger proteins that cannot enter the pores do not equilibrate with the interior volume of the gel bead and therefore move through the column faster than smaller proteins that can enter the pore and are momentarily retained because they are essentially removed from the main column flow for a short period of time. Molecules that are completely excluded from the beads elute in what is termed the void volume (V_o) of the column, which is approximately 30% of the bed volume. Molecules that can completely equilibrate inside the pores of the beads elute in the inclusion volume (V_i), typically around 80% of the bed volume. Since this process occurs repeatedly as a molecule moves down the column, longer columns tend to display better resolution of different size species. A typical column size may be $3\text{ cm} \times >100\text{ cm}$ and have a flow rate of 1–2 ml/min. Also, because larger molecules move faster, they elute first from the column while smaller species elute later. Because of this, size exclusion chromatography (SEC) can be used in an analytical mode, with the appropriate standards, to determine the molecular weight of proteins and other macromolecules in their native state. This is particularly good for analyzing the native molecular weight of multi-subunit proteins or protein complexes. Because gel beads cannot be made with a single uniform pore size, SEC gels separate over a range of molecular weights with different gels separating in different size ranges. Like ion-exchange gels, SEC gels are made of similar materials including cellulose, agarose (Sephacrose), dextran (Sephadex), and acrylamide (Sephacryl, Bio-gel P).

Adsorption Chromatography

The term 'adsorption' chromatography is generally used to refer to adsorptive processes that are not mainly due to ionic interactions or dependent on a 'biological' affinity. Chief among these are Dye-ligand chromatography and Inorganic Adsorbent chromatography.

Dye-ligand chromatography

Certain organic dyes that can be attached to a solid support have been found to bind to certain types of proteins. The most widely used of these are Cibacron Blue and Procion Red that have a good affinity for NAD and NADP dependent proteins such as dehydrogenases, with the latter being more selective for NADP enzymes. Other dyes are also available depending on the manufacturer. Elution of the protein is usually performed by increasing the ionic strength but if there is sufficient hydrophobic interaction this can increase the binding affinity. For dehydrogenases, the particular coenzyme, NAD(H) or NADP(H), can be used but these are relatively expensive.

Hydrophobic interaction chromatography

This type of chromatography relies on the interaction of hydrophobic areas on proteins with a matrix containing hydrophobic groups in the presence of high salt concentrations. The high salt promotes the hydrophobic interaction and the proteins are eluted by decreasing the salt concentration. As such, it is well suited as a step after ammonium sulfate precipitation or IEX where the target protein is eluted at a relatively high salt concentration.

This should not be confused with reversed phase chromatography (RPC) or hydrophilic interaction chromatography (HILIC). These techniques are usually not well suited for proteins because they employ water miscible organic solvents such as acetonitrile that can disrupt protein structure or cause aggregation.

Inorganic adsorbent chromatography

The most common and useful among these for proteins is hydroxyapatite, a crystalline form of calcium hydroxyphosphate. The mode of action is not well-defined and it is a matter of trial and error to determine if it is useful for a particular target protein. Other adsorbents that have been employed include silica gel and alumina. In practice, these adsorbents are most often used in industrial processes to remove contaminants and some unwanted proteins. They could also be used for batch adsorption early in a protocol.

Affinity Chromatography

Affinity chromatography is a general term referring to a separation based on a biological affinity for a specific molecule such as an antibody, a sugar, or some other particular molecular recognition process (Chapter 9 in *Current Protocols in Protein Science* has many useful articles).

Immunoaffinity chromatography

This chromatography entails the covalent attachment of an antibody for a particular protein to a solid support. As such, the column can be highly selective. However, because antibodies tend to have a very high affinity for their antigen, eluting the bound protein can be problematic.

Lectin affinity chromatography

Lectins are molecules that specifically bind sugars, and this type of chromatography is used to selectively bind glycoproteins. Immobilized concanavalin-A and wheat germ agglutinin are the most widely used because they have wide specificity and are relatively inexpensive. There are many other lectins that are commercially available but they are not generally used for protein purification because they are expensive. Also, even if a variety of lectins were used, they might not yield a pure protein since other proteins with similar sugars would tend to co-purify.

Metabolite affinity chromatography

If a particular metabolite that is a substrate, product, or cofactor for an enzyme can be immobilized on a matrix and still retain binding affinity for the enzyme, it can be effective and often very specific. One example is the use of 5'-AMP and 5'-ADP Sepharose (and similar materials) for proteins that

bind nucleotides. These materials may also exhibit ion-exchange characteristics since they contain charged groups.

Affinity tag chromatography

The development of recombinant DNA technology and the PCR led to a major breakthrough in protein purification by enabling the widespread use of affinity tags. It is safe to say that, today, many more purification protocols employ this technique than do not. Not only is it easy and relatively inexpensive, it often results in sufficient purification in just a single step. It has proven to be so effective that it should be considered a potential part of every protein purification procedure. This type of chromatography depends on a specific interaction between a molecule that has been covalently attached to a protein (usually as a polypeptide extension) and some specific solid support that has affinity for the 'tag.' The most common and widely used type is immobilized metal affinity chromatography (IMAC) through the addition of a sequence of 6 histidine residues to the amino- or carboxyl-terminus of a protein that specifically interact with metals such as nickel or cobalt that have been immobilized on a solid support. Other notable and commonly used tags include FLAG, Strep-Tactin, glutathione S-transferase (GST), and maltose-binding protein (MBP) (Kimple *et al.*, 2013). In addition, a variety of specific proteolytic cleavage sites can be placed between the tag region and the protein so that the tag can be removed after purification. This is not always necessary but there are instances where the tag can interfere with protein function. Many commercially available protein expression vectors have built-in proteolytic cleavage sites for removing affinity tags.

Affinity tags are generally of two types, those that function mainly in affinity recognition for purification and those that aid in keeping the expressed protein soluble. Often the tag can serve both purposes, such as MBP. A discussion of all the affinity tags that have been developed would take more space than is available here, but good review articles are available (Kimple *et al.*, 2013; Lichty *et al.*, 2005).

The use of tandem affinity tags have also proven useful for reducing the background of nonspecifically bound proteins that may survive a purification using only a single tag. Two affinity tags with different specificity are engineered onto the same protein that is then passed through the two appropriate affinity matrices in succession.

A variation on the tandem tag method has also been used successfully in the isolation of eukaryotic proteins from cell extracts where they are not expressed at very high levels and isolation by a single tag does not result in protein of sufficient purity (Günzl and Schimanski, 2009; Gloeckner *et al.*, 2009). While the technique does not usually produce very high levels of protein (sometimes only picomolar amounts) the protein is usually very pure and sufficient enough for some analytical techniques such as partial sequencing by mass spectrometry. This approach has proven quite useful for the isolation of protein complexes or proteins composed of nonidentical subunits.

Migration in an Electric Field

Proteins can be separated by their differential migration in an electric field. Three such methods that have been adapted for

preparative purposes are electrophoresis, isoelectric focusing and isotachopheresis. However, they are not widely used for preparative purposes due to their expense, complexity, and generally low yield. On the other hand, gel electrophoresis, especially SDS gel electrophoresis, has seen much success as an analytical method and is a major technique in assessing protein purity.

Protein Crystallization

Today, protein crystallization is usually performed for the purpose of structure determination by X-ray crystallography (McPherson, 2004). However, back when protein purification methods were less sophisticated, a crystallization step was sometimes employed for purification. The common method for crystallization is to form a supersaturated solution of the protein with precipitants such as ammonium sulfate or polyethylene glycol. Crystallization can be the ultimate purification step since the crystals are made up of a repeating array of a single protein. However, the down side is that many proteins need to be very pure already in order to induce them to crystallize. Nonetheless, some proteins can crystallize from fairly heterogeneous solutions and even micro-crystals will suffice. Crystallization is also a good method to stabilize proteins for storage. These days, one does not usually see a crystallization step in most modern purification procedures, but it bears keeping in mind for those times when it could be helpful.

Evaluating Purity

As mentioned at the beginning of this article, assessment of protein purity is really the demonstration that no other proteins are present. This of course is dependent on the sensitivity and resolving power of the analytical methods used. By far the most common method used is SDS gel electrophoresis and staining the proteins in the gel with dye or silver-based stains. Another good indication of purity is a constant specific activity across a chromatographic peak. Mass spectrometry, although very sensitive and useful, is not recommended by itself because not all proteins may be detectable since they may not all ionize successfully or equally. Likewise, the presence of additional protein signals can be misleading unless all the spectra can be compared quantitatively.

A Final Word

Traditionally, every protein purification procedure was tailored to the specific protein being purified and a successful purification often had an element of art as well as science. Nonetheless, there was probably always more than one way to purify any protein and most procedures could probably be improved in some way. As technology improves, the approach that one takes also tends to change. For instance, recombinant DNA technology has produced a kind of 'one size fits all' situation where a large number of diverse proteins can be purified with essentially the same protocol, such as the

hexa-histidine metal affinity tag. However, it would be a mistake to think that this is the answer to all purification challenges, especially those involving eukaryotic proteins, and especially when they are expressed in other than bacterial cells or must be isolated from tissues or cell cultures. Thus, one would do well to be familiar with the whole repertoire of purification techniques for those times when the 'art' of protein purification still has a role.

Sequencing Proteins by Chemical Techniques

Early Studies

Life processes require the accurate translation of genetic information, which is basically linear in nature, into proteins, which generally only function correctly when they have folded to their proper conformation. Thus, proteins have both a linear component (amino acid sequence; referred to in the earlier literature as the primary structure) that is dictated by genomic DNA (via RNA copies) and a three-dimensional structure that is dictated by the sequence (although often helped by auxiliary proteins and covalent modifications, usually termed posttranslational modifications or PTMs) (Anfinsen, 1993). However, as described below, the elucidation of protein sequences has evolved into a relatively simple task during the last 75 years, it is still not possible to predict the exact structure that any given unknown sequence will adopt, although considerable progress has been made in achieving this goal. The realization, some 50 years ago, that proteins with recognizably related sequences also had related structures spurred the development of molecular evolution and, as the numbers of protein structures from both X-ray crystallography and two-dimensional NMR increased, so did the number of predicted structures from model building. Today, with the availability of vast amounts of predicted protein sequence data from an ever widening collection of organisms derived from high-throughput (or next Gen) nucleic acid sequencing, the challenges of understanding protein structure/function properties tend to be ones of identifying and understanding PTMs, particularly transient ones, and the dynamic nature of the multiplicity of protein-protein interactions that characterize cellular processes.

The elucidation of peptide and protein sequences began in earnest about the time of the Second World War. At that juncture, the covalent structure of peptides (the Hofmeister-Fischer hypothesis) was well accepted (Rosenfeld, 2012) but there was some uncertainty about whether they were composed of random or ordered sequences of amino acids. It was also uncertain whether they had 'open' N- and C-termini or occurred as closed loops that lacked free ends. These issues were definitively resolved by Sanger and his colleagues with the determination of the sequence of insulin (Sanger, 1964), which in its mature state is composed of two distinct polypeptide chains covalently linked by two interchain disulfide bonds. These studies, which required some 12 years to complete, depended on the earlier work of Martin and Synge (1941), who introduced chromatography (initially on paper) as a means of separating complex mixtures and the development of a method for tagging free amino groups with fluorodinitrobenzene (now known as Sanger's reagent). Using strong and weak (partial) acid hydrolysis and eventually proteolytic enzymes (pepsin, chymotrypsin, and trypsin) and expanding their fractionation techniques to include ionophoresis and ion-exchange chromatography, they completed the sequence determination and elucidated the pairing of the three disulfide

bonds (there was one intrachain linkage). They also introduced the strategy of deducing the full sequence from overlapping peptides that became the basis for protein sequencing for the next 25 years (Schroeder, 1968; Blackburn, 1970).

The Move to Larger Proteins

As important as these studies were, it was clear that insulin was a relatively small protein (in some estimations it was on the borderline between a peptide and protein) and the elucidation of its sequence had been greatly facilitated by the fact that it was isolated in two smaller pieces (after the disulfides were cleaved by performic acid oxidation) and that it lacked methionine and tryptophan, two amino acids that can present problems during analytical manipulations. Fortunately there were two additional technological advances 'in the wings' that proved to be essential in allowing the application of Sanger's methods and strategy to larger and more complicated proteins. The first of these was a highly reproducible analytical method for doing amino acid analyses (Moore and Stein, 1993) and the second was a different method for tagging and determining the N-terminal residue of a peptide that could be applied sequentially (Edman, 1950). Both of these key contributions were in fact already being developed during the time Sanger was sequencing insulin but neither were fully adopted until after he had completed that task.

The development of the automated amino acid analyzer was the work of Stein and Moore and their colleagues (Moore and Stein, 1993) and utilized ion-exchange chromatography for separation and the ninhydrin reagent for detection and quantification. The resin that was finally adopted for this purpose was a sulfonated cross-linked polystyrene known as Dowex 50. In addition to its ion-exchange properties, it had considerable hydrophobic character that allowed the separation of the nonpolar amino acids as well as the ones bearing polar side chains and provided quantitative identification on appropriately calibrated instruments. In the early stages of development, a single analysis required about 24 h but constant improvements eventually shortened the time to less than an hour. Coincidentally, as a part of this work, they also developed the fraction collector (Stein and Moore, 1948), which is still, in its various manifestations, a staple of any biochemistry laboratory. Both the analyzer and the fraction collector were subsequently developed commercially.

The new N-terminal method, first developed for this purpose by Edman (1950), was based on the reaction of the α -amino group of a peptide with phenyl isothiocyanate in dilute alkali, which produced a phenylthiocarbamyl derivative. The modified peptide would, on exposure to acid, cyclize to a substituted anilinothiazolinone that removed the first residue from the remainder of the peptide. Subsequent conversion of the unstable thiazolinone to the corresponding phenyl thiohydantoin (commonly referred to as a PTH-amino acid) allowed for its identification by a variety of analytical

techniques. Under conditions that limited the amount of acid cleavage of other peptide bonds in the remainder of the peptide during cyclization, the reaction could be repeated to identify the second amino acid (now the new N-terminus) and so on (Figure 1). When originally applied to isolated peptides derived from enzymatic digests (that were generally in the range of 2–20 amino acid residues), it could also be carried out in a subtractive mode (Hirs *et al.*, 1960) whereby the composition of the peptide was determined before and after each cycle of the Edman degradation to determine what amino acid had been removed (by difference). The availability of high-speed, quantitative amino acid analyses made this a particularly popular approach in the 1960s and early 1970s. The usefulness of the Edman degradation to sequencing studies was greatly enhanced by the adoption of (nearly) anhydrous trifluoroacetic acid (or similar compounds) that allowed cyclization to occur with only trace amounts of background hydrolysis (and minimal degradation of some amino acids) (Konigsberg and Hill, 1962). This was particularly true when this invaluable method was subsequently also automated (Begg and Edman, 1967).

The Role of Separations Methodology

Beside its modest size, insulin was also available to the Sanger group in relatively large amounts in homogenous form, a prerequisite for chemical sequencing studies. It is therefore not surprising that most of the studies that followed Sanger's pioneering effort were with proteins that were also relatively easy to purify and obtain in substantial amounts (see Schroeder, 1968, for a description of a representative listing of these early efforts). These tended to be extracellular moieties that were found in fluids or other conveniently obtained rich sources.

Nonetheless, the substantial improvements in separations technology that followed the Sanger work played a very significant role in making available more and more proteins for sequence analysis. Two of the most important of these were ion-exchange resins suitable for protein separations, such as substituted celluloses and gel filtration media. These latter resins, consisting of cross-linked dextrans (Sephadex) or polymerized and cross-linked acrylamide (Bio-gel), basically fractionated protein mixtures on the basis of size, and gave a new dimension to purification schemes that was largely independent of separations based on charge. Performed in tandem they were very effective. Of course there were many additional methods that were modified or introduced, such as gel electrophoresis, isoelectric focusing, reverse phase high-performance liquid chromatography (HPLC), and affinity chromatography among others, that substantially increased the arsenal of separations procedures. When any or all of these were used in conjunction with the older bulk methods, such as alcohol or ammonium sulfate precipitation, sophisticated multistep protocols to purify even relatively rare proteins began to be fairly commonplace by the mid-1960s. It was not till recombinant technology became available that these often laborious protocols became largely passé and the need to sequence proteins by chemical means (other than to obtained partial sequence data to construct oligonucleotide probes for cloning experiments), for the most part, disappeared.

The development of separations technology also played a very significant role in preparing peptides and fragments for sequencing. In early studies the fragments generated by enzymatic cleavage were generally small and soluble (although there was invariably an insoluble core that often contained longer fragments, whose further fractionation always presented significant challenges). In fact, until automated sequencing

Figure 1 Schematic diagram of sequential cycles of Edman degradation.

became routinely available, peptides much longer than 10 residues would require some sort of further reduction in size since manual Edman degradation rarely went much further than that. Thus it was common to use several types of enzymes, with differing specificities, as a means to generate enough soluble peptides to get complete coverage of the sequence being determined. Since, after trypsin, the specificity of the proteases available was less precise and, therefore, less reliable this often proved to be a problem. For the most part, mixtures of soluble peptides from enzymatic digests were amenable to fractionation by the same resins used for separating amino acids (Dowex 50, its basic counterpart, Dowex 1, and Amberlite IRC 50, which was a carboxylate resin and hence a weak anionic exchanger). Gel filtration resins, with low-molecular weight cutoffs, and in later years, HPLC, were also very useful.

The wide-scale introduction of the automated protein sequencer in the early 1970s had a material impact on strategy and hence the technology employed. At first, it was most valuable in determining the N-terminal sequence of whole proteins but that soon led to the realization that by creating bigger fragments these could be analyzed as if they were proteins in their own right (and unlike the whole protein, which was often blocked by an acetyl group if it was a cytoplasmic protein from a eukaryotic cell, they had an accessible N-terminus). Employing cleavage strategies that produced fewer cuts and thus larger pieces had already appeared in more ambitious studies of significantly larger proteins. Many of the more successful methods for creating bigger fragments depended on chemical reagents (as opposed to enzymes). The most important and widely used of these was cyanogen bromide (CNBr) (Gross and Witkop, 1961), a highly reactive and toxic substance that in strongly acidic solutions, for example 70% formic acid, reacts only with the thioether of methionine side chains to produce a sulfonium salt that then results in cyclization leading to cleavage of the adjacent peptide bond (and leaves homoserine lactone in the place of the methionine in the C-terminal position of each fragment generated, except the one derived from the C-terminus of the protein). Generally the large fragments produced were due to the relatively rare occurrence of methionine. Various other methods, often depending on the introduction of one or more modifications first, were also developed (Blackburn, 1970).

The creation of big fragments that were easy to analyze by automated sequencing and were effective in subdividing large sequences into more manageable sized pieces also produced their own challenges. Being derived from denatured proteins and therefore essentially without structure themselves, they were often difficult to solubilize and purification schemes for them usually required more extreme solvent conditions than the fractionation of the smaller soluble mixtures. Gel filtration was particularly useful in these applications because it was better suited to tolerate such solvents (including detergents).

It is noteworthy that the spinning cup technology of Begg and Edman (1967) became much more amenable to the analysis of smaller peptides with the discovery that polybrene[®] added to the reaction mixture materially reduced losses of sample, thus greatly enhancing its value in large-scale sequence projects.

Challenges and Limitations

The strategy of determining a complete sequence by piecing together overlapping fragments depended almost exclusively on N-terminal sequencing. Determining C-terminal sequences was considerably more difficult and there was no sequential degradation method comparable to the Edman degradation for attacking peptides from the C-terminal end despite several efforts to develop one (Inglis, 1983). Hydrazinolysis (Akabori *et al.*, 1952), which converted every residue in a peptide or protein to a hydrazide except the C-terminal one, was a relatively complex procedure with a number of confounding problems associated with identifying the one free amino acid and was not practical for routine peptide sequencing. The only method that was widely used was timed hydrolysis by carboxypeptidases A and/or B (Blackburn, 1970). The latter was very efficient in removing lysine and arginine and hence worked well on most tryptic peptides but its counterpart, carboxypeptidase A, gave much more variable results as some residues were released so rapidly they could not be distinguished while others were completely intransigent. Since this method was very much sequence-dependent, it could rarely be depended on to give more than two or three reliable identifications and often produced nothing at all.

This one-sided approach to collecting data often undermined reliable peptide alignments and residue assignments. Many times overlaps were made on the basis of a single residue, which was risky at best, and the conclusion that there were no residues that had been overlooked in the final proposed sequence usually depended on the known molecular weight and the amino acid composition that had been determined (based on this number). It is illustrative that Sanger worked for many years under the illusion that insulin had a molecular mass of about 12 000 Da rather than the actual figure of about 6000 Da and it was certainly welcome news to him that he only had ~50 residues to determine rather than 100 he had originally thought (Sanger, 1964). This did become less of a problem when methodology for determining subunit structure and protomer molecular weights, particularly sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) (Weber and Osborn, 1969), became routine (and basically replaced much more sophisticated and expensive methods, such as analytical ultracentrifugation).

Good practice also dictated that it was important to establish the identity of each residue in two different ways, i.e., in two different peptides, that added to the challenge of assembling the final proposed sequence (that this rule was often violated which led to a significant number of incorrect assignments that were only subsequently uncovered with the advent of nucleic acid sequencing). Automated sequencer runs of whole proteins and large fragments could often identify 40–50 amino acids with few if any undetermined residues. The repetitive yield of the reactions of each cycle and the accumulated loss of material determined the limit of obtaining useful data. Using polybrene[®] added to the reaction vessel and a modified coupling program, Thomas *et al.* (1981) reported the identification of 79 residues out of 83 present (with only 4 unidentified sites, 1 of which was ultimately identified as asparagine with N-linked carbohydrate attached, and all of which occurred in the last 18 cycles of the run) using ~600

nmols of a naturally occurring fragment of the γ -subunit of 7S NGF, which probably represents the practical limit of this technology. As sequence determinations increasingly became dependent on sequencer data and relatively long stretches were achieved, the number of identifications determined only a single time also increased. To some degree this was offset by improved technology, such as the introduction of the gas-phase sequencer (Hunkapiller *et al.*, 1991) that largely displaced the spinning cup methodology of the original Begg-Edman design, and significantly increased accuracy and sensitivity. However, in the end, the development of nucleic acid sequencing effectively made the problem no longer moot.

The stability and reactivity of the 20 acids that make up most proteins in biology are not the same and accordingly presented variable issues in sequence studies. Several amino acids were known to be partially destroyed by the conditions of acid hydrolysis commonly used (6 N HCl at 110 °C for 24 h, *in vacuo*) such as serine, threonine, and tryptophan. In the last case, this was probably more related to contaminants than to any inherent instability. These, and other residues, are also partially destroyed in the cyclization and conversion of the thioazolinones to the hydantoins, which was a major problem in sequencer analyses. Cysteine and its oxidized form, cystine, were recognized early on as unstable amino acids (Sanger converted the 6 half-cystines in insulin to cysteic acid) and it was a routine step to modify them to a stable form. Until it was determined that disulfide bonds were introduced in the endoplasmic reticulum (ER) for proteins that were destined to be exported through the ER-Golgi continuum to the extracellular environment and that intracellular proteins, except for a few special cases, had only cysteine residues, newly isolated proteins were reduced and alkylated routinely without regard to what form they were in the isolated protein. Because this obscured the original state of the side chain, the number of Cys residues was usually reported as half-cystines, a term that did not distinguish their state in the native proteins. Since the conditions for strong oxidation also modified several other residues, milder reactions such as the introduction of carboxymethyl and carboxamidomethyl groups were favored. There are several other modifications also available, depending on the type of subsequent analysis envisioned. Converting half-cystines to trypsin-sensitive sites by converting them to *S*-aminoethyl derivatives is an example. The availability of the germane reagents in radioactive form was also a useful way to count half-cystine residues (as labeled peptides) following tryptic digestion and was an effective way to determine the true molecular weight based on the minimal molecular weight calculated from the independently determined half-cystine content (Angeletti *et al.*, 1971).

The determination of disulfide pairing was a commonly encountered problem in early studies because these tended to focus on proteins found in easily obtained materials, such as body fluids, that were by definition from extracellular environments. Although the half-cystine residues could be assigned from residues converted to stable derivatives, such as was done with insulin, the connectivity could only be ascertained from peptides derived from the unmodified protein. Because it was already recognized by Sanger (1964) that disulfide interchange could occur around pH 7 and higher, most chose pepsin as the enzyme of choice, which functions in

much more acidic conditions. The basic procedure employed was to isolate the cystine-containing peptides to homogeneity, cleave them by oxidation (or reduction and alkylation) and identify the two contributing halves (Spackman *et al.*, 1960). Since at this point the sequence was usually known, the peptides did not have to be sequenced extensively to make unequivocal identifications. The spacing of some half-cystine residues (not bonded to each other) was sometimes so close that pepsin cleavage between them was not achieved and then other enzymes or chemical methods were required to generate unique cystine peptides (see, e.g., Angeletti *et al.*, 1973). When a protein contained multiple disulfide bonds, the fractionation of these linked peptides to homogeneity was often challenging. One method that was relatively simple and proved to be quite effective was diagonal electrophoresis (Brown and Hartley, 1966). The digest containing the cystine peptides was separated by paper electrophoresis in one dimension, exposed to performic acid vapor (forming cysteic acid *in situ*) and then re-electrophoresed under the same conditions at 90° to the original direction. The pairs of peptides making up the original disulfide-linked entity moved off the diagonal because of their changed charge properties although all the non-cystine peptides did not. The cysteic acid containing peptides were then eluted and identified by partial sequence analysis (sometimes amino acid composition alone was sufficient). With the advent of the new ionization techniques in mass spectrometry, the identification of cystine peptides in unfractionated samples became possible saving a great deal of experimental manipulation and thus time (see, e.g., Raffioni *et al.*, 1988).

The presence of naturally occurring PTMs, with the exception of carbohydrate, was largely ignored and was not a point of focus until the combination of cell signaling studies and proteomic technology demonstrated the extent to which they are present. Despite the fact that it is now known that modifications, such as phosphorylation, occur extensively affecting a very high proportion of intracellular proteins (Gnad *et al.*, 2011) (and even some extracellular ones), these hardly ever were detected in chemical sequence analyses. This is probably mainly due to instability during handling and to low occupancy of many if not most of the modifications. One exception to this was the introduction of proteolytic cleavages, which were readily detected and accurately mapped in many proteins. However, distinguishing between cleavages introduced posttranslationally (see, e.g., Thomas *et al.*, 1981) from proteins synthesized as separate entities was not easily accomplished until genomic sequence data became readily available.

Other Sequencing Methodology

Mass Spectrometry

The applicability of mass spectrometry to determining amino acid sequences was recognized in the late 1950s to early 1960s by a number of laboratories, particularly those of Biemann (MIT) (Biemann *et al.*, 1959) and Lederer (Paris-Orsay) (Barber *et al.*, 1965). Although clearly there were advantages to this approach including the ability to determine a number of residues at the same time and in the presence of

contaminating peptides, the principal problem was the lack of volatility of peptidic material and this proved to be a major limitation until greatly improved desorption-ionization methodology was developed. Early workers were able to achieve sequence data by this approach by derivatizing various functional groups in relatively short peptides or taking advantage of natural modifications. Fortuitine, a mycobacterial peptidolipid of nine residues that contained equal amounts of eicosanoic and docosanoic acids in amide linkage with the N-terminal valine, two residues of *O*-acetyl threonine, two residues of *N*-methyl leucine, and a C-terminal methyl ester was an example of the latter (Barber *et al.*, 1965). *N*-Methylation of peptide bonds, among several other modifications, which increased volatility, was subsequently adopted for other sequence determinations (Blackburn, 1970). For the most part, early sequence studies with mass spectrometry were effective in studies with cyclic peptides and antibiotics or when used in conjunction with other chemical approaches as exemplified by the sequence analysis of the heptadecapeptide amide, gastrin (Agrawal *et al.*, 1969) and were generally limited to peptides of <10 residues in length. They were also laborious and insensitive, owing in part to the losses incurred during the modification reactions.

The value, and hence the use, of mass spectrometry for determining peptide and protein sequences dramatically changed with the introduction of new technology that overcame these problems. Beginning in the early 1980s, first fast atom bombardment (FAB) and then matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) allowed the analysis of peptides of ever increasing size to eventually include proteins (without any prior modification) to produce highly accurate masses (Siuzdak, 1996). When analyzed with tandem mass spectrometers, peptides could be isolated and then subjected to fragmentation (by collision with inert molecules) to produce a series of sequentially truncated ions that corresponded to the original sequence. Three different ion pairs (six different types of ions) can result from cleavage of the three different types of covalent bonds found in the polypeptide backbone but the most commonly encountered are *b* and *y* ions (see Figure 2; Roepstorff and Fohlman, 1984). A completely overlapping set (*b* ions are derived from the N-terminus and *y* ions are derived from the C-terminus) will yield the entire sequence. When this methodology was connected with chromatographic systems that were compatible with ESI, it was possible to continually analyze the effluent to produce a very large number of at least partially sequenced peptides (Burlingame, 1989).

Figure 2 Fractionation pattern of peptides that occurs in tandem mass spectrometric analyses as proposed in Roepstorff and Fohlman (1984).

However, by the time of the new millennium when this methodology had already reached this level of sophistication (and beyond), the need for sequencing individual proteins had been long eclipsed by advances in nucleic sequencing (see below). Thus, mass spectrometric sequencing rather found its most useful applications in the unbiased identification of proteins (inferred from sequenced peptides), usually in unfractionated, complex samples (but also in smaller scale experiments) for the purposes of (1) analyzing expression, elaborating the composition of protein complexes/machines and elucidating partners in protein-protein interactions and (2) determining/localizing PTMs. These types of studies are at the core of the new field of proteomics (Bradshaw and Burlingame, 2005).

Because most proteomic measurements depend on pre-formed databases that have been mainly assembled from annotated genomic sequences or other nucleic acid based analyses, the use of this methodology (or of the chemical methodology described above) to determine new, unknown sequences is fairly limited. Even proteins from more exotic species can often be deduced from homologous proteins, whose sequence has already been determined, using programs such as BLAST (Altschul *et al.*, 1990). However, on occasion it is necessary to determine a sequence *de novo* and there are two basic approaches referred to as top-down and bottom-up analyses. The latter depends on the fragmentation of the proteins, usually by trypsin, and the identification and sequencing of the corresponding peptides, a procedure that is entirely analogous to the overlapping chemical approaches pioneered by Sanger and colleagues for insulin (Sanger, 1964). The large-scale protein identification (Washburn *et al.*, 2001) experiments also use this strategy but do not depend on achieving full coverage of the sequence since identification can virtually always be reliably accomplished with a single sequence of 6–7 amino acids in length although rigorous studies usually require at least two such peptides. Identifications based on sequenced peptides cannot distinguish splice variants unless the peptide covers a juncture corresponding to two exons. It can identify individual variants from unique peptides but the absence of peptides in a mass spectrometric analysis cannot be used to infer the absence of that variant. When the intention is to determine a new sequence (or identify modified residues in an already known protein), essentially complete coverage of the sequence is necessary and, as in the earlier chemical approaches, usually requires more than one set of peptides. Top-down analyses (Kelleher *et al.*, 1999) basically start with a pure protein (or a relatively simple mixture) and subject the entire sample to fragmentation in the mass spectrometer. This results in very complex spectra and the presence of a great number of fragment ions that must be resolved and identified. This challenging approach has been increasing successful with new advances in mass spectrometric analyses, mainly electron capture dissociation (ECD) and, more recently, electron-transfer dissociation (ETD), and proteins of over 200 residues have been extensively sequenced in a single experiment (Peng *et al.*, 2014). This type of analysis has also been applied to large fragments and is often termed ‘middle down.’ The main value of this methodology, which can only be expected to improve, is most likely to be in the identification and localization of PTMs, particularly in proteins, such

as histones, that carry multiple kinds and sites of modifications in complex and varying patterns (Garcia, 2010).

Inferring Protein Sequences from Nucleic Acid Sequences

The acquisition of protein sequence information by chemical methodology reached its peak in the late 1970s. However, even with many improvements in this technology, it remained a relatively labor-intensive and time-consuming endeavor. Thus, the codevelopment of cloning techniques around that time that allowed the preparation of DNA copies of mRNA (called complimentary or cDNA) and reliable DNA sequencing techniques that were faster and cheaper, which spawned the methodology of recombinant DNA (Berg, 1993), soon displaced chemical methodology as a source of protein sequence information. Two different methods for sequencing DNA were independently developed by Sanger (1993) and Gilbert (1993) for which they shared the Nobel Prize in Chemistry for 1980. Sanger's procedure eventually was adopted as the method of choice. Thus he established the methodology for determining the sequences of both proteins and nucleic acids, an achievement of inestimable importance to further studies in cell and molecular biology. Initially, knowledge of at least a portion of the amino acid sequence of a target protein was necessary in order to synthesize DNA probes to screen appropriate libraries to find the corresponding cDNA sequence and the techniques of protein sequencing were highly valuable in achieving this. Eventually, however, DNA manipulations, in general, and DNA sequencing, in particular, became sufficiently efficient that this information was no longer necessary and which finally culminated in the rapid determination of whole genomes, including that of *Homo sapiens*. The accumulation of genome sequence data on a massive scale continues unabated. As a result the overwhelming majority of protein sequence information that has been collected and is available today, spanning the entire range of living (and some that are extinct) organisms, is based not on direct measurements but on translated nucleic acid sequences. Indeed there is still between 10 and 20% of the predicted human proteome that has not yet been directly identified in an appropriate sample by any technique (Kim *et al.*, 2014; Wilhelm *et al.*, 2014). Although nucleic acid sequencing has provided a plethora of information (that would have required decades to obtain by direct protein sequencing, even with the advances in mass spectrometry), there are consequences that have presented new challenges, the most important of which is the detection of splice variants (as alternatively expressed forms of a given gene) and PTMs. While the number of genes predicted to make up the human genome plummeted during the process of elucidating it (from somewhere ~150 000 to the eventually determined number of ~20 000), the number of splice variants and particularly the extent of PTM in the actual expressed proteome rose dramatically. In the end it became clear that the concept of 'one gene, one protein' (Beadle and Tatum, 1941; Berg and Singer, 2003) was a vast oversimplification and that rather than depend on a huge multiplicity of unique genes to drive biological complexity, nature simply found ways to modify a more restricted group of chemically distinct proteins (and thus increase the

number of functions they could perform or participate in) through splicing and chemical modification instead. Unfortunately, simple DNA sequences are not reliable indicators of what splicing events will occur and under what conditions and consensus sequences for PTMs do not guarantee that a site will actually be modified. Furthermore, the majority of PTMs are governed by only very loose rules regarding site characteristics and in many cases there are no discernible rules at all. Thus the objectives of protein sequence analyses have shifted from determining the order of amino acids to determining exon usage and downstream covalent modifications. Mass spectrometry, in its various manifestations, is overwhelming the method of choice for such analyses.

Sequence Comparisons

One of the earliest observations to arise from chemical sequencing studies was the realization that proteins of the same function in different species or of similar but not identical function in the same (or other) species showed readily detectable similarities that could be deduced by simply aligning the two. Proteins that showed such a relationship were then said to be homologous, meaning that they had a common ancestry. The term homology came from biological studies and, before sequence analysis, was based primarily on the comparison of anatomical structures. Two things (structures) were said to be homologous if they had a common ancestry. Protein chemists co-opted this word to apply to related protein sequences (assuming, as they did, that they had evolved from common genes) and further manipulated the term to imply degrees of similarity. Thus they introduced qualifiers such as partial, weak, strong, etc. that, since homology as defined by the biologists was a yes or no condition, changed the meaning of the word. Despite an extensive polemic, this modified use of the term has remained in common usage. Sanger and colleagues (Brown *et al.*, 1955; Harris *et al.*, 1956) established that the same protein in different species were similar by studying the insulins from four additional species: pig, sheep, horse, and whale (his original sequence analysis was carried out with bovine insulin). He found them to be highly similar with only a three residue sequence, located in the intrachain disulfide loop of the A chain, showing substitutions. Thus the number of identical residues in the two chains was 48/51 (=94%). Human hemoglobin chains and myoglobin also showed similarities but in this case the number of identities was considerably lower (see Figure 3). However, it was also obvious that many of the substitutions in other positions were by residues of similar chemical character and it was concluded that these might be well tolerated if the proteins also showed three-dimensional similarity as well. These two proteins both function to transport oxygen through the agency of a heme prosthetic group, although in quite different cellular locales, and they have distinctly different subunit structures (often referred to as quaternary structure) as myoglobin is a monomer and hemoglobin is a heterotetramer ($\alpha_2\beta_2$), where the α and β chains also show the same kind of relatedness, albeit more extensive than that found in the myoglobin comparisons. Thus the myoglobin/hemoglobin comparison represents the evolution of function. These concepts were cemented by early

Figure 3 Comparison of the amino acid sequences of hemoglobin α chain and myoglobin. Boxed residues are identical; those highlighted in yellow are chemically similar.

Figure 4 Three-dimensional structures of hemoglobin α chain, myoglobin, and leghemoglobin.

sequence studies on various serine proteases (trypsin, chymotrypsin, elastase, and thrombin) (Walsh and Neurath, 1964; Hartley *et al.*, 1965; Hartley, 1968) and the carboxypeptidases (Bradshaw *et al.*, 1969). All of these examples were also the subject of early crystallographic analyses using X-ray diffraction and it became quite clear that the similarities in amino acid sequence were also manifested in similarities in the folding of the polypeptide chain. Thus, for example, the folding of the polypeptide chain of myoglobin and either of the hemoglobin chains is obviously similar, even without further computerized analyses. Figure 4 compares the structure of these two and a third heme proteins found in plant roots termed leghemoglobin; all have essentially the identical three-dimensional structure. In fact it has ultimately been shown that the three-dimensional structure of a protein is a more sensitive indication of homology, particular with proteins that are distantly related. When sequence comparisons fall below 25% identities (a region Doolittle (Doolittle, 1981) rightfully termed the 'twilight zone'), the certainty that two proteins are truly homologous becomes considerably more difficult to ascertain by sequence data alone.

The evolution of species variants and of functional variants has since been defined in more specific terms: orthologous sequences are from proteins derived from the same ancestral sequence now found in different species and paralogous sequences are from those proteins still present in the same species that arose via a gene duplication event (see Figure 5). Once

two copies of the gene exist, one is free to accumulate point mutations leading to potential new function. When this function exerts some sort of advantage, the changes will become fixed in the population but will be recognized as a paralog of the original gene product as long as a sufficient amount of the original sequence remains unaltered. A paralogous group may constitute a family containing a large number of members, such as the protein kinases (Manning *et al.*, 2002), which retain the common capability of phosphorylating certain protein side chains utilizing ATP as donor but recognize different sequence motifs containing the target residue, or may be composed of only two members. In the case of the kinases, their catalytic function has not been altered but their substrate specificity has been. Enzymes (or other protein types) that basically retain their catalytic function but show differential expression in cells and organs are usually termed isozymes (isoforms) and can sometimes be exploited as a biomarker if they are elevated (or decreased) and are released into the circulation in a certain disease or condition (see, e.g., Peng *et al.*, 2014). Paralog groups may also be found in a variety of species if the speciation event in question occurred after the gene duplication.

Although the paralogous gene duplications cited above basically correspond to the generation of complete copies, partial duplications are also well known. Indeed many proteins consist of identifiable domains (which often coincide with exons) and these clearly can be copied and recopied during the gene duplication events that marked evolution,

Figure 5 Examples of orthologous and paralogous relationships.

thus ending up in variety of proteins, sometimes totally unrelated (Tang *et al.*, 1978). This phenomenon is called ‘domain swapping’ and can occur multiple times in larger proteins. The ‘EF hand,’ a Ca^{++} binding domain composed of two α -helices on either side of a short loop containing the carboxylate ligands that bind the metal that was first identified in fish parvalbumin (Kretsinger *et al.*, 1971), is widely distributed in mammalian proteomes, being found in a large number of proteins of quite varied function that are regulated by Ca^{++} .

Concluding Remarks

The determination of linear sequence information, first from proteins and then nucleic acids, has paralleled the history of research in the biological sciences for the past 75 years. It can be viewed in three principal phases: the chemical determination of protein sequences, the determination of nucleic acid sequences (and the inferred sequences of many additional proteins) and the determination (and identification) of proteins from partial sequences, their modifications (PTMs) and their interacting partners in unfractionated samples by high-throughput mass spectrometry. Each phase basically represents a paradigm shift in our understanding of the fundamentals of cell biology and, importantly, each was dependent on the previous phase for its inception and development. Although sequence and structure will never by themselves completely explain the workings of the cell, they are indispensable information that will be required to reach this goal.

Posttranslational Modifications: Key Players in Health and Disease

Introduction

The one gene–one enzyme hypothesis introduced in 1941 proposed that each gene was responsible for producing a single enzyme that in turn participates in a single step in a specific metabolic pathway (Beadle and Tatum, 1941). Although this was a necessary first step in our understanding of protein translation, since that moment, the concept of protein synthesis has evolved greatly. We now know that one gene can be transcribed into many mRNAs which in turn produce several proteins; and that, although sharing a core amino acid sequence, the resultant proteins may bear many different reversible or irreversible chemical alterations, including the covalent incorporation of lipids, carbohydrates, and other chemical groups. Collectively, the modifications that proteins undergo, either during synthesis or after translation are fully completed, and are designated ‘posttranslational modifications’ (PTMs).

Biologically, PTMs are involved in a variety of cellular activities, such as regulation of gene expression, activation/deactivation of enzymatic activity, protein stability or turnover, and mediation of protein–protein interactions. Therefore, the characterization of PTMs provides invaluable insight into the cellular functions underlying the origin of these processes. In the present article we provide a brief but comprehensive overview of the most important PTMs and explain their major contributions to protein and cellular function.

Proteolytic PTM of Proteins

Before presenting the PTMs that result from reversible or irreversible anchorage of molecules of differing nature to the amino acid core, we first discuss one of the most important, ubiquitous and irreversible protein modifications: the limited and highly specific hydrolysis of peptide and isopeptide bonds of a protein by proteases. Proteases exist in all orders of life and constitute one of the largest enzyme families in humans (Puentes *et al.*, 2003). Limited proteolysis is especially important as part of the maturation process for peptide hormone precursors. A clear example of the posttranslational processing of a protein is the cleavage of pro-opiomelanocortin (Bicknell, 2008), a precursor whose differential cleavage by specific proteases within the secretory pathway gives rise to various product peptide hormones with diverse biological activities. Interestingly, most of the proteases that carry out these maturation cleavages, as well as many other proteases, are synthesized as inactive precursors, termed zymogens, that also require proteolytic processing (often autocatalytic) in order to become proteolytically active.

In addition to involvement in prohormone maturation, proteolysis also regulates a wide array of cellular processes; for example, removal of the signal peptide, which is essential for correct secretory protein maturation. Pathological alterations

in regulated proteolysis result in the loss of many important regulatory processes (e.g., peptide hormone deficiency arising from nonfunctional maturation enzymes). There are a host of other proteolytic events important to essential processes that control cellular homeostasis, such as cell death and cell proliferation, as well as pathological processes such as inflammation, cancer, or arthritis (Barrett *et al.*, 1998). Advances in the identification of proteolytic cleavage sites have been powered by the development of techniques that permit the identification of N- and C-terminal peptides, and these methodologies are now increasingly used for identifying protease substrates and cleavage sites (Rogers and Overall, 2013).

Trimming of peptides by peptidases also falls under the category of proteolytic modification of proteins. Cells contain many enzymes which trim proteins and peptides by a small number of amino acids; these enzymes are termed aminopeptidases and carboxypeptidases. As two examples, the initiating N-terminal methionine of many proteins is removed by a cytosolic aminopeptidase (Bradshaw *et al.*, 1998); and secreted proteins require the action of specific carboxypeptidases that remove basic residues left on the C-terminus following convertase action (Canaff *et al.*, 1999).

Phosphorylation

Although there is currently no method to readily assess the occurrence of every known PTM on a specific protein, a recent study reported the relative abundances of many PTMs found experimentally from high-quality proteome-wide data (Khouri *et al.*, 2011), and deposited in an updated resource (see PTMCuration in ‘Relevant Websites’). Figure 1 depicts the relative abundance of the various PTMs, where phosphorylation appears as the most widespread PTM among proteins. The term phosphorylation appeared in 1954 when it was observed that an enzyme (a protein kinase) was able to transfer a phosphate onto another protein (Burnett and Kennedy, 1954). Immediately following this discovery, other researchers (Fischer and Krebs, 1955; Sutherland and Wosilait, 1955) showed that an enzyme involved in glycogen metabolism was regulated by the addition or removal of a phosphate, suggesting that reversible phosphorylation (dephosphorylation) could somehow regulate enzyme activity. The concept of reversible phosphorylation has stood the test of time, and it is now known that the simple addition of a phosphate group is able to greatly alter the conformation of a protein, modifying its structure and function, while dephosphorylation switches the protein back to its original conformation. The balance between phosphorylation and dephosphorylation provides a host of cellular proteins with varying conformations that directly modify their activities.

The transfer of phosphates onto proteins is catalyzed by a variety of enzymes in the cell, called protein kinases, which

Figure 1 Relative abundance of the most widely distributed PTMs.

share certain biochemical characteristics (reviewed in Sefton, 2001). Kinases constitute 2% of the genome and fall into 10 different families. All kinases possess the ability to remove phosphate from the chemically energy-rich molecule ATP and place it onto the side chain of specific amino acids within proteins. The hydroxyl groups (-OH) of serine, threonine, and tyrosine side chains are by far the most common kinase targets. A second class of enzymes is responsible for the reverse reaction, in which phosphates are removed from a protein. These enzymes are termed protein phosphatases, and they are also frequently regulatory enzymes.

Often, cells use a sequential string of phosphorylation events, termed a 'phosphorylation cascade' as a response to an external signal in order to produce an integrated response to a cellular event. In a kinase cascade, a given kinase is activated by phosphorylation and in turn phosphorylates other kinases, amplifying the original signal. Several different kinase cascades can respond to a cellular signal and become integrated in the final phosphorylation events. For example, cellular insulin signaling is mediated by a phosphorylation cascade that begins with the tyrosine phosphorylation of the insulin receptor, which then induces the cytoplasmic binding of IRS-1 (insulin receptor substrate 1) to these receptors. The receptor then phosphorylates several tyrosine residues within IRS-1, which enables IRS-1 to activate several downstream signaling pathways. Discoveries such as this have uncovered the importance of phosphorylation in pathologies such as diabetes (Nandi *et al.*, 2004). Many other key cellular signaling processes depend directly upon the correct functioning of various

phosphorylation cascades. New kinases are still being discovered; for example, the secreted kinase that likely phosphorylates all secreted proteins, FAM20C, was discovered only in 2010 (reviewed in Tagliabracci *et al.*, 2013); this enzyme phosphorylates proteins at Ser-X-Asp/Glu motifs.

Glycosylation (*N*- and *O*-linked)

Glycosylation is one of the most common and complex forms of PTM of proteins (Ferguson *et al.*, 2009), and in the human genome, about 1–2% of the total genome corresponds to genes that are directly involved in glycan assembly (Schachter and Freeze, 2009). This process involves a covalent attachment of one or several carbohydrate chains to the amide group of the asparagine (*N*-glycoprotein), or, less frequently but still quite often, to the hydroxyl group of serine or threonine (*O*-glycoprotein). *O*-linked glycosylation can occur either in the cytosol or the secretory pathway, while *N*-linked glycosylation occurs only on proteins made within the secretory pathway.

N-linked glycosylation begins with assembly of a ubiquitous 14-residue high-mannose precursor on dolichol, a lipid in the membrane of the rough endoplasmic reticulum (ER). This preformed oligosaccharide then is transferred to specific asparagine (Asn) residues within a consensus sequence (Asn-X-Ser/Thr) on nascent polypeptide chains within the ER lumen. Further modifications to *N*-linked oligosaccharides occur in the ER and are completed in the Golgi complex, with terminal sialylation or 'capping' occurring in the trans-Golgi

network (Lodish, 2000). The co-translational addition of sugars is thought to stabilize the growing protein chain and block inappropriate side chain interactions. An elaborate system of quality control exists to ensure that secretory proteins are correctly folded, and carbohydrates play an important role in this process. N-linked chains are generally about 2–3 kDa in size. On the other hand, O-linked oligosaccharides, which are bound to serine, threonine, or hydroxylysine residues, are generally short, often containing only one to four sugar residues. Protein-bound oligosaccharides contribute heavily to folding, stability and the final bioactivity profile of glycoproteins; other glycosylation events such as the addition of such as mannose 6-phosphate also perform the important role of lysosomal targeting of these proteins.

Since correct glycosylation is essential for obtaining and supporting the normal biological activity of proteins, impairment of glycosylation will lead to the synthesis of glycoproteins with reduced or lost function. The ability of carbohydrates to modulate the activities of proteins has been previously assessed (Lis and Sharon, 1993). Many pathological states are characterized by changes in the carbohydrate structure of cellular glycoproteins, and most of these are due directly to defective activity of specific glycosidases or transferases. As a consequence of the widespread occurrence and variety of glycosylation events, this PTM is the primary cause of variability among proteins with similar amino acid cores.

In healthy people, glycoproteins have a normal protein isoform pattern that may change in a characteristic manner in different diseases. Disturbances of glycosylation may be either acquired or congenital (Schachter and Freeze, 2009). As one of many examples, altered N-glycosylation has been found in several pathologies linked to neurodegenerative diseases. Specifically, in Alzheimer's disease the tau and beta-amyloid peptide precursor proteins, which contribute to the major pathological hallmarks of neurofibrillary tangles and amyloid plaques, respectively, have both been found to be glycosylated (Schedin-Weiss *et al.*, 2013). Considering that the N-glycosylation of proteins was thought to occur within the secretory pathway, i.e., only on extracellular (secreted) proteins or on the extracellular domains of membrane-bound proteins, it is especially intriguing that the cytosolic protein tau was found to be N-glycosylated in Alzheimer's but not in control brains (Wang *et al.*, 1996). Another disease in which altered N-glycosylation occurs is cancer progression, for example, in gastric carcinogenesis (Pinho *et al.*, 2013). O-glycosylation may also be altered in cancer, and it is thought that the altered pattern of surface sugars on tumor cells may be involved in metastasis and/or immune evasion (Wang *et al.*, 1996).

Congenital disorders of glycosylation (CDG) mostly result from genetic defects leading to the deficiency or loss of a specific enzyme activity involved in glycan (sugar) synthesis and processing, or to a deficiency of specific transporters (Freeze *et al.*, 2009; Cylwik *et al.*, 2013a,b). At this moment, 30 CDG subtypes have been identified at a molecular and biochemical level. The clinical manifestations of CDGs are heterogeneous and may be highly variable within the same subtype. Novel insights into certain extremely complex glycosylation pathways have led researchers to a reclassification of the group of CDGs, and today CDGs comprise not only the formerly known multisystem glycosylation defects, but also

certain tissue-specific glycosylation defects. Since diagnosis and treatment depend heavily on the particular underlying glycosylation defects, progress in understanding glycosylation pathways will contribute to improved patient treatment (reviewed in Vodopietz and Bodamer, 2008).

N-Acetylation

Lysine acetylation is a PTM that refers to the addition of an acetyl group (CH_3CO) to the lysine side chain (N-acetylation). This modification was originally observed in abundant proteins such as tubulin and histones, conferring microtubule stability or an increase in transcriptionally-active chromatin, respectively (reviewed in Close *et al.*, 2010). Histone acetylation and deacetylation are the processes by which the histones on lysine residues within the N-terminal tail and on the surface of the nucleosome core are acetylated and deacetylated during normal gene regulation (Grunstein, 1997). Positively charged lysine residues in histone proteins interact electrostatically with negatively charged phosphate groups along the DNA backbone. Acetylation reduces these interactions and loosens the DNA, facilitating its transcription. Since histones were identified as the first substrates of proteins that catalyze the removal of an acetyl moiety, these enzymes were termed histone deacetylases (HDAC) – even though some do not actually target histones. In fact, lysine acetylation has also been found to regulate transcription factors and coactivators including p53 or PGC1 α (Mellert and McMahon, 2009; Yang and Seto, 2008), and this PTM is especially abundant in the mitochondria, where it has been found in 20% of mitochondrial proteins, including metabolically important enzymes and proteins whose activity is linked to life span regulation (Kim *et al.*, 2006).

Recent work indicates that lysine acetylation may be comparable in scope with that of other major PTMs. Although high-resolution mass spectrometry (MS) using a leukemia cell line allowed for the identification of more than 1500 acetylated proteins, a key feature of the acetylome is its cell-type specificity (Choudhary *et al.*, 2009). Notwithstanding this, protein acetylation has been identified in enzymes involved in glycolysis, gluconeogenesis, the tricarboxylic acid and urea cycles, fatty acid metabolism, and glycogen metabolism, as described in hepatocytes (Zhao *et al.*, 2010). This PTM is now seen as a major mechanism by which the activity of multiple substrates is regulated, with key consequences on aging and on diseases associated with aging (Wagner *et al.*, 2011).

Protein N-terminal acetylation is one of the most common covalent modifications of proteins. This modification can occur on the initiating methionine residue, which forms the main target of acetylation, or can take place after the removal of this N-terminal methionine residue. Together, these modifications occur on the vast majority of eukaryotic proteins; in the case of mammalian systems, it has been suggested that up to 90% of the proteins are N-acetylated (Helbig *et al.*, 2010).

Amidation

C-terminal α -amidation is a common secretory PTM mediated by the hydroxylase and lyase activities of a bifunctional

enzyme, peptidylglycine α -amidating monooxygenase (PAM) (Prigge *et al.*, 2000). Amidation serves as a rate-limiting process of the final steps in bioactive peptide synthesis for amidated peptides and therefore is subject to regulation (Eipper *et al.*, 1992). α -amidation has also been implicated in a variety of pathological processes such as neural dysfunction (Bousquet-Moore *et al.*, 2010) and hypertension (Shimosawa *et al.*, 2000).

Methylation

The recognition of protein methylation as an important regulator of protein interactions has grown in recent years. Methylation of proteins at arginine and lysine residues is a PTM involved in many different cellular processes, such as signal transduction, protein translocation, maturation of hnRNPs, or processing of mRNAs and transcriptional control (reviewed in Erce *et al.*, 2012). The functional impact of this PTM has been best characterized in histone proteins (reviewed in Lee *et al.*, 2005), although lysine methylation of other proteins has been emphasized as a prominent participant in non-histone protein bioactivities (Huang and Berger, 2008).

Lipid Modification (Lipidation)

Protein Prenylation

The hydrophobicity of a protein can be modified by the covalent addition of lipids. For example, several proteins, such as Ras and Ras-related GTP-binding proteins undergo prenylation (the addition of isoprenoid groups) in order to be able to attach to the particular cell membrane where they carry out their function. There are two major prenylation modifications: attachment of farnesyl (15-carbon) or geranylgeranyl (20-carbon) isoprenoids to conserved cysteine residues at or near the C-terminus (Zhang and Casey, 1996).

GPI Anchoring

Anchoring of a protein to the membrane can also occur by the binding of the glycolipid glycosylphosphatidylinositol (GPI); this is another PTM that, although not among the most abundant PTMs (Figure 1), is nonetheless ubiquitously found in all kingdoms (Ikezawa, 2002). GPI-linked proteins are thought to be preferentially located in specialized portions of the cell membrane known as lipid rafts, suggesting a high level of organization within plasma membrane microdomains.

Myristoylation and Palmitoylation

Lipidation by myristoylation (the attachment of a 14-carbon fatty acid to the N-terminal glycine of a protein) can have numerous effects, including influencing protein–protein interactions, enhancing interactions of the protein with either organelle or plasma membranes, and altering protein stability (Wright *et al.*, 2010). Palmitoylation, which represents the addition of a 16-carbon fatty acid to a C-terminally located cysteine, also greatly enhances the hydrophobicity of proteins,

contributes to their membrane association, and plays a significant role in subcellular trafficking of proteins between membrane compartments, as well as in modulating protein–protein interactions. In contrast to prenylation and myristoylation, palmitoylation is usually reversible (Charollais and Van Der Goot, 2009), providing cellular flexibility in membrane attachment.

Oxidative Stress-Related PTMs

During the conversion of the flux of nutrients into energy, mitochondria generate intermediates for biosynthesis and reactive oxygen species (ROS) (Cheng and Ristow, 2013). Although ROS may serve as second messengers in signal transduction cascades, any imbalance in ROS production causes oxidative damage to nucleic acids, lipids, and proteins (Cheng and Ristow, 2013). Indeed, ROS and oxidative stress have been consistently identified as important pathogenic components of metabolic diseases (Whaley-Connell *et al.*, 2011). Accordingly, several studies have been aimed at characterizing the oxidatively modified forms of proteins that ultimately contribute to the development of a pathological status and associated metabolic disorders (Evans *et al.*, 2003). Targeted proteomic approaches have been developed to investigate ROS-related PTMs, and these are referred to as ‘redox proteomics.’ Among the redox-related PTMs, hydroxylation, carbonylation, and nitrosylation have been particularly frequently described in adipose tissue, liver, and pancreas (Peinado *et al.*, 2014).

Hydroxylation

This modification consists of the introduction of a hydroxyl group (–OH) into a protein; the most abundant hydroxylated proteins are the structural proteins collagen and elastin, in which hydroxylation of prolines and lysines plays an important role in certain protein cross-linking reactions which contribute to tissue stability. Ascorbate (vitamin C) is a required cofactor for prolyl and lysyl hydroxylase, and a deficiency of this vitamin results in the collagen disease known as scurvy. Additional cross-linking of lysines – also required for tissue structural stability – is accomplished by lysyl oxidase, a copper-requiring enzyme that catalyzes the formation of bridging aldehydes between lysines within collagen and elastin. Aberrant protein hydroxylation as a consequence of increased ROS species has been associated with a higher apoptotic rate in various pathological processes; for example, hydroxylated proteins are especially abundant in mitochondria during the development of type 2 diabetes (Deng *et al.*, 2010).

Carbonylation

Protein carbonylation can also occur from ROS-induced oxidation reactions. Protein carbonyls can be generated through the incorporation of carbon monoxide into the side chains of lysine, arginine, proline, and threonine. Elevated protein carbonylation levels have been associated with several human metabolic diseases (Dalle-Donne *et al.*, 2003).

Nitrosylation

A growing body of experimental evidence has demonstrated that S-nitrosylation of cysteine residues within a broad functional spectrum of proteins is responsible for the ubiquitous influence of nitric oxide (NO) on cellular function (Hess *et al.*, 2005). The emerging recognition that protein S-nitrosylation is involved in a multiplicity of cellular signal transduction pathways points to the possibility that dysregulated S-nitrosylation could contribute to pathophysiologies characteristic of a wide range of disease states (Foster *et al.*, 2009). The relatively recent development of improved methods for the analysis of protein S-nitrosylation has permitted the identification of numerous S-nitrosylated proteins (SNO-proteins) whose levels of S-nitrosylation can be altered in disease, including prominent disorders of the cardiovascular, musculoskeletal, and nervous systems (Foster *et al.*, 2009).

Ubiquitin and Targeted Protein Degradation

When proteins become damaged or misfolded, they must be degraded to prevent the acquisition of potentially abnormal activities. One of the major mechanisms for the elimination of cellular proteins involves the protein complex known as the proteasome. In eukaryotic cells the proteasome comprises a catalytic core as well as regulatory complexes. Proteins destined to become degraded by the proteasome are first tagged by attachment of ubiquitin, a 76-amino acid polypeptide, to lysine residues. The process of ubiquitin attachment to the substrate protein involves multiple ubiquitin additions and thereby constitutes a PTM that drives the protein to the proteasome. Many proteins involved in the regulation of cell proliferation and differentiation, apoptosis, and DNA repair undergo regulated degradation via proteasomal action. In humans, deregulation of the proteasome can contribute to the pathogenesis of a variety of human diseases, such as cancer, myeloproliferative diseases, and neurodegenerative disease (Schmidt and Finley, 2014). More extensive information on ubiquitination can be found in the article 'Ubiquitination' (see 'See also' section).

γ -Carboxylation

γ -Carboxylation is a PTM carried out by the enzyme γ -glutamyl carboxylase during the biosynthesis of vitamin K-dependent proteins (Stenflo and Suttie, 1977). γ -Glutamyl carboxylase oxidizes vitamin K while simultaneously adding CO₂ to protein-bound glutamic acid to form γ -carboxyglutamic acid (known as 'Gla'), which allows these proteins to bind calcium (carboxylation). γ -Carboxylated proteins are involved in both bone formation and in blood coagulation. A deficiency of vitamin K – found in leafy green vegetables such as romaine lettuce, spinach, and kale – can result in problems with hemostasis, and drugs such as warfarin which interfere with vitamin K synthesis serve as powerful anti-coagulants. γ -Carboxyglutamic acid has been observed in both vertebrates and invertebrates, and γ -carboxylase activity is also found in nearly all mammalian tissues (Furie *et al.*, 1999). The

widespread distribution of both Gla and γ -carboxylase activity supports the idea that this PTM plays other, less well-understood biological roles (Kulman *et al.*, 2007).

Conclusions: Many More PTMs Exist, and There Is Cross Talk between Them

The importance of PTMs, both common and uncommon, is now emerging as an additional level of control in biological processes. It should be stressed that although protein phosphorylation and glycosylation are the most widely studied modifications, many other PTMs also occur *in vivo* that we have not discussed here; although several are well known (i.e., sulfation; Figure 1) the function of others is still under study (i.e., sumoylation). During the last years a number of reviews have been written that explore the importance of sulfation and sumoylation, as well as other PTMs such as methylation (Hickey *et al.*, 2012; Paul and Snyder, 2012; Chen *et al.*, 2011). Furthermore, it should be noted that many different PTMs (as well as occurrences of the same PTM) may occur on the same protein, which suggests that there is PTM cross talk. An interesting example is the case of the p53 tumor suppressor protein. The p53 protein may undergo up to six different PTMs, including phosphorylation, acetylation, and sumoylation, that likely modulate its interactions with other proteins and collectively affect its stability and activity (Xu, 2003). It is clear, however, that we are still far from a complete understanding of how the coexistence of several PTMs within a given protein can work together to impact its overall function, and how a given PTM can regulate a wide number of cellular processes, from cell proliferation to cell death.

Given that any covalent modification that occurs *in vivo* on a protein can be considered a PTM, there is a continuous flux of proposals for new PTMs. Mass spectroscopy will continue to play an important role in PTM identification. For example, a new PTM was recently discovered that appears to take place on numerous mammalian proteins; this PTM originates from the reaction of lysines with a primary glycolytic metabolite, 1,3-BPG (bisphosphoglycerate). This reaction both increases the size and inverts the charge potential of the modified residue from positive to negative (Moellering and Cravatt, 2013). Continuous updating of the panel of existing and new PTMs will be required in order to gather comprehensive information on all of the potential modifications that occur on a given protein, and their effects on function. This process has been assisted by the development of predictive algorithms which take advantage of rapid advances in data processing never imagined 20 years ago. A variety of new bioinformatics programs now permit the prediction of potential PTMs within a given protein; and several very useful internet nodes compile all of these predictive programs. Two representative nodes are the CBS Prediction Servers and the ExPASy servers (see Relevant Websites section).

Introduction

Within cells, proteins are the workhorses that both drive signal transduction and govern cellular responses. Although proteins perform a myriad of functions, the structure of a single, globular protein can be broken down into distinct structural levels: primary, secondary, tertiary, and quaternary structure. The primary structure of a protein describes the sequence of amino acids, with directionality from amino- to carboxy-terminus, which comprises a polypeptide chain. The secondary structure of a protein refers to the structural elements – for example, α -helices and β -strands – that form the protein into more than simply a string of amino acids. The tertiary structure of a protein describes how the primary and secondary structural elements fold into the overall three-dimensional arrangement of the polypeptide. Finally, the quaternary structure describes the higher order assembly of multiple polypeptides into oligomers. Although some proteins function as monomers of a single polypeptide chain, many are assemblies of copies of one (i.e., homo-oligomers) or multiple polypeptides (hetero-oligomers). The combination of these structural levels dictates the function of a single protein by influencing aspects of its biochemical reactivity, regulation, protein–protein interaction specificity, and posttranslational modifications.

These general classifications of protein structure are somewhat limited, as evolution promotes the formation of more complex proteins and structural elements for diverse biological and chemical functions. As the expanse of both sequence and structure space is explored, the classification of protein structure and function expands to include structural motifs and units that convey specific functionality within proteins. To this end, the building blocks of many complex proteins are often domains.

By definition, investigation of protein domains and their functions is guided by understanding protein structure at a molecular level. Examining the structural characteristics of proteins enable scientists to understand important facts about protein function and to synthesize what is known to make further predictions regarding the function of uncharacterized proteins. Further, elucidation of protein structure coupled with phylogenetic analysis allows for generation of informed hypotheses involving strategies and themes in protein evolution. Here we discuss protein structure and domains; common themes in domain functionality; advances in bioinformatic tools that improve prediction of domains and domain functionality; and applications of domain research within protein science and cell biology.

Protein Structure: Motifs, Folds, and Domains

The classic definition of a protein domain is that a polypeptide chain comprising the domain remains highly stable such that it retains its three-dimensional structure and biological

function independent of the rest of the larger protein (Richardson, 1981). It is important to distinguish a protein domain from other primary and secondary structural units. A domain refers to the structure and function of a portion of a protein, not simply the sequence. In other words, the amino acid sequence may suggest the presence of a specific domain, but the presence of a defined domain may only be confirmed by linking the structure and function of that region. To this end, primary sequence alignments of proteins can provide important clues in identifying both the presence of protein domains, and defining known protein domain boundaries. Standard biochemical, biophysical, and bioinformatic methods for assessing the presence of a domain and its boundaries are discussed later in this article.

Domains are independent functional units that contribute to the tertiary structure of a globular protein. Domains range in size from less than 40 amino acids to around 700 amino acids (Orengo *et al.*, 2002) with an average around 100 amino acids (Wheeler *et al.*, 2000). The energetics of protein folding influences the general limits of domain size, although other factors, including metals, disulfide bonds, other cofactors, and hydrophobic interactions, also constrain size of a domain (Xu and Nussinov, 1998).

The structure of individual domains and small proteins is defined by the organization of secondary structure and super-secondary structures, also called motifs. Motifs are defined by the composition and organization of α -helices, β -structures, and unstructured loops and often comprise repeating units within a protein region. Motifs may be simple – for example, helix-loop-helix motifs – or more complex – for example, α/β -barrels. Excellent references about protein structure motifs illustrate the range from simple to complex in the organization of protein secondary structure (Branden and Tooze, 1999).

Although the structure of domains is defined by secondary elements and motifs, the presence of a motif or series of motifs does not dictate the function of a domain or a protein. Rather, individual or multiple motifs organize to form a protein fold (Figure 1). A three-dimensional fold, however, is distinct from a protein domain. Although a domain preserves both function and structure, the term fold only describes the overall three-dimensional structure. Further, domains may be described and classified by their three-dimensional fold, but the presence of a fold does not necessarily dictate the presence of a specific domain. A series of proteins may share common structural motifs or folds, but possess unrelated functionality.

A classic example of a family of proteins that possess structural similarity due to the presence of a common fold and motif, but with low sequence similarity and a wide variety of functionalities are the α/β hydrolases (Nardini and Dijkstra, 1999). The α/β hydrolases are defined by the presence of a complex mixed α/β structural motif, but range in functionality from those lacking catalytic activity – for example, the *Arabidopsis thaliana* α/β hydrolase KARRIKIN INSENSITIVE2 (KAI2; Guo *et al.*, 2013) – to a host of lipases, esterases, and proteases

Figure 1 A hierarchical representation of protein structure. This graphic illustrates the various levels of protein structure from least structured (primary structure, top) to most structured (folds and domains). Because domains are functional–structural modules within proteins, the progression from purely structural units to functional units is illustrated.

across numerous species and kingdoms (Nardini and Dijkstra, 1999). Although structural variance exists within this protein family, this example outlines the importance of distinguishing between architectural similarity and functional redundancy.

The organization of protein motifs, folds, and domains has been laid out in a number of databases and resources. Some examples of such databases are outlined later in this article.

Protein Domain Functions

Protein domains are the smallest functional unit of a globular protein. It is important to acknowledge the vast number of structural domains that have been identified. Each of these structural domains conveys a specific cellular function. Because space limitations prevent in-depth analysis of all protein domains, below is a brief discussion of representative domains classified by general function: interaction and binding domains, DNA-binding domains, and enzymatic/catalytic domains.

Interaction and Binding Domains

The function of many protein domains is to facilitate protein–protein interactions by binding to specific recognition motifs or structural features in various ligand molecules (Table 1; Figure 2). These targets may include posttranslational modifications, such as phosphorylated tyrosine, serine, and threonine residues. For example, the Src Homology 2 (SH2) domain is highly conserved in tyrosine kinase signaling pathways and facilitates protein–protein interaction by recognizing phosphotyrosine-containing sequences (Liu *et al.*,

Table 1 Summary of representative interaction and binding domain recognition targets. Different interaction/binding domains target specific molecules and target sequences

Interaction and binding domain	Target
C2	Membrane lipids and Ca^{2+}
EH (Eps15 homology)	S/T-N-P-F-Z
EF-hand/calmodulin	Ca^{2+}
EVH1 (enabled/VASP homology 1)	D/E-Z-P-P-P
PB1 (Phox Bem1p)	Charged surfaces
PDZ	X-X-S/T-X-V-Cterm
PH (pleckstrin homology)	PIP2, PIP3
PTB (phosphotyrosine binding)	Z-X-N-P-X-pY
SH2 (Src homology 2)	pY-X-X-Z
SH3 (Src homology 3)	R/K-X-X-P-X-X-P
WW	P-P-X-Y
14-3-3	R-S-X-pS-X-P

Note: X = variable residue; Z = hydrophobic residue.

Figure 2 Representative protein–protein interaction domains. Protein surface representations of the v-Src SH2 domain (PDB: 1SHA; Waksman *et al.*, 1992), insulin receptor substrate-1 PTB domain (PDB: 1IRS; Zhou *et al.*, 1996), and the SEM-5 SH3 domain (PDB: 1SEM; Lim *et al.*, 1994) are shown with target peptides bound (gold stick). Phosphotyrosine (pY) peptides are bound to the SH2 and PTB domains and a poly-proline peptide is bound to the SH3 domain.

2012). Similarly, phosphotyrosine binding (PTB) domains also recognize phosphotyrosines, but with a different sequence context (Kafasla *et al.*, 2012). The identity of the phosphorylated residue can also confer interaction specificity. For example, 14-3-3 proteins target phosphorylated serine and threonine residues (Aitken *et al.*, 1995).

Distinctive amino acid sequence features also provide recognition sites for interaction domains. Src homology 3 (SH3), enabled/VASP homology 1 (EVH1), and WW domains recognize poly-proline repeats (Kay, 2012; Renfranz and Beckerle, 2002; Ilsley and Sudol, 2002), whereas, Eps15 homology (EH) and PDZ domains bind specific amino acid sequence motifs (Table 1; Confalonieri and Di Fiore, 2002; Ye and Zhang, 2013). Alternatively, surface features of macromolecules may mediate interactions. For example, the Phox Bem1p (PB1) domain uses concentrated patches of positive and negative charge located, respectively, on opposite faces of the domain for front-to-back interaction with other PB1 domain-containing proteins (Sumimoto *et al.*, 2007). Other domains, such as C2, EF-hand, and pleckstrin homology (PH) domains, facilitate protein interactions either with specific lipid molecules or ions (Corbalan-Garcia and Gomez-Fernandez, 2014; Kawasaki *et al.*, 1998; Lemmon *et al.*, 2007).

Figure 3 Representative protein–DNA interaction domains. The helix–turn–helix domain of the phage 434 repressor (PDB: 2OR1; Aggarwal *et al.*, 1998) and the basic leucine zipper domain of the cAMP responsive element-binding protein (CREB; PDB: 1DH3; Schumacher *et al.*, 2000) are shown as ribbon diagrams. The helix–turn–helix structural motif of phage 434 repressor is indicated by HTH.

DNA-Binding Domains

Although some interaction domains facilitate the interaction with other proteins, membrane lipids, or signaling molecules, a separate subsection of domains enable interaction of a protein with DNA. Such domains are common in transcription factors (Figure 3). Among the most prevalent of DNA-binding domains in prokaryotes are the helix–turn–helix and winged–helix structures that place an α -helix for interaction with bases in the major groove of the target DNA sequence (Harrison and Aggarwal, 1990; Brennan, 1993). In eukaryotes, the basic leucine zipper (bZIP) and zinc-finger domains are common transcription factor features. The bZIP domains share two characteristics – a hydrophobic, leucine-rich dimerization region and a lysine/arginine-rich DNA-binding region (Ellenberger, 1994). In contrast, zinc-finger transcription factors often consist of multiple ‘fingers’ and can recognize either DNA or RNA (Hall, 2005; Klug, 2010). Likewise, another common DNA-binding domain is the B3 domain, which is conserved in higher land plants (Romanel *et al.*, 2009). Some transcription factors also contain protein–protein interaction domains. For example, the signal transducers and activators of transcription (STAT) proteins are phosphorylated on a tyrosine to mediate homodimerization via an SH2 domain, which leads to formation of a DNA-binding site (Chen *et al.*, 1998).

Enzymatic and Catalytic Domains

Proteins domains are not limited to serving as mediators of interactions, but can also provide enzymatic functions. In eukaryotes, protein phosphorylation is a common posttranslational modification in up to 30% of cellular proteins (Ubersax and Ferrell, 2007). Although phosphorylation occurs in a diverse range of proteins and amino acid sequence contexts, all protein kinases share a conserved three-dimensional structure defined by a canonical catalytic domain of approximately 250 amino acids (Ubersax and Ferrell, 2007). The specificity for tyrosine versus serine/threonine is determined by the depth of the active site cleft with additional structure features, including various protein interaction domains, leading to proximal and distal determinants of substrate recognition (Ubersax and Ferrell, 2007). Although not as abundant as kinases, protein phosphatases also share a common catalytic domain fold with combinatorial interaction between shared catalytic subunits

and one of a large number of regulatory subunits to provide target specificity (Shi, 2009).

Intrinsically Disordered Domains

Although protein domains, by definition, are classified and described by their overall ordered structure, an increasing number of protein domains and proteins are characterized by their intrinsic lack of ordered tertiary structure. These domains, or proteins, are described as intrinsically disordered domains (IDDs). IDD are generally considered to be flexible and unfolded in physiologically relevant conditions (Fink, 2005; Uversky and Dunker, 2010). It is hypothesized that conformational flexibility provided by overall lack of structure allows for wider, heterogeneous interaction within cells. The alternate conformations of IDDs may be induced by post-translational modification, or interaction with a potential substrate (Dunker *et al.*, 2008; Wright and Dyson, 2009). The importance of IDDs in human disease – for example, α -synuclein (Dunker *et al.*, 2008) – and in plant developmental signaling – for example, Aux/IAA repressor proteins and SAUR proteins (Wang and Estelle, 2014), for example, is shifting our understanding of proteins and protein structure. In this way, understanding and characterizing the lack of structure of these IDDs is as important as the efforts imposed upon understanding protein structure. This is an emerging frontier area in protein structure and function.

Identifying and Classifying Protein Domains

The hallmark of identifying the presence of a protein domain is to understand its three-dimensional structure. Visualizing protein structure occurs largely through two separate techniques: X-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy. Through the use of these two techniques, scientists are able to generate models of the three-dimensional structure of a protein and analyze the structure to understand the function. To bypass these specialized techniques; however, bioinformatics platforms can also predict the presence of domains based on a number of different factors. Overall, the combination of these techniques enables both direct assessment of protein functionality and an understanding of how proteins work within a cell.

Structural Determination by Protein Crystallography and NMR Spectroscopy

There are two main methodologies used for generating a three-dimensional model of a protein. The most commonly used method is X-ray crystallography, which involves six major steps: (1) protein purification, (2) growing protein crystals, (3) optimizing the crystals for uniform crystal packing, (4) obtaining X-ray diffraction data, (5) phasing the data to generate an electron density map, and (6) building and refining a structural model of the protein. A major limitation in acquiring a structural model by X-ray crystallography is the generation of diffraction-quality crystals. To achieve crystal packing, the protein must be highly ordered and, for the most

part, rigid. Extended regions of disordered polypeptide, or the existence of major conformational changes within a protein or a protein subunit or domain may prevent crystallization.

NMR spectroscopy is also a powerful tool for obtaining protein structural data. In contrast to X-ray crystallography, NMR spectroscopy only requires soluble protein – i.e. no crystal formation. Instead, any soluble, stable protein that is highly ordered can be labeled with ^{15}N and ^{13}C . Then, using solution NMR spectroscopy, one can obtain structural information from the two-dimensional chemical shift data (Wüthrich, 1990). Using NMR for obtaining protein structural data has two major limitations. The proteins must be relatively small (<70 kDa) and any disordered regions will not yield a single structural result; rather, conformationally flexible regions will appear in a number of possible states. Depending upon the final application of the structural data, this second limitation may either obstruct analysis or provide interesting insight into the dynamics of the protein structure.

Ultimately, both X-ray crystallography and NMR spectroscopy are extremely powerful and complementary tools for generating high resolution atomic models of globular macromolecules. Both methods allow for identifying domain boundaries visually: if the general expected structure of the domain is known, obtaining the structure of the overall protein will allow for definitive identification of the domain boundaries. In addition, both techniques are especially useful for investigating the structure of a single protein domain if the boundaries of the domain are either already known or inferred – by definition, protein domains are independent, stably folded structural units. Moreover, protein domains are usually much smaller than an entire protein, which eliminates one of the major limitations of NMR.

Despite the independently stable nature of protein domains, understanding where domain boundaries exist can be difficult and unclear. One of the major methods for experimentally determining domain boundaries is through limited proteolysis. In limited proteolysis, proteins are nonspecifically digested in solution by specific or nonspecific proteases, such as trypsin, chymotrypsin, or proteinase K. The general principle of limited proteolysis is that, in solution, the folded, globular protein will not be cleaved, whereas disordered regions flanking highly ordered globular domains are proteolyzed. Thus, incubation of a protein domain with a protease will, over a time course, trim the protein to its more rigid core, thereby affording the globular domain.

Proteins subjected to limited proteolysis may be further examined by a number of analytical methods, including mass spectrometry for identification of domain boundaries and preparation of the trimmed protein for structure determination by either X-ray crystallography or NMR spectroscopy. A classic experimental approach is to monitor limited proteolysis reactions over time by SDS-PAGE and then subjecting the final product to in-gel trypsin digest followed by mass spectrometry to elucidate the core structure of the domain in question (Stroh *et al.*, 2005; Gao *et al.*, 2005). Limited proteolysis has also proven to be a useful tool in crystallizing previously recalcitrant proteins (Dong *et al.*, 2007; Wernimont and Edwards, 2009).

Although these approaches work for studying protein structure, the study of IDD requires other approaches. For

example, X-ray crystallography cannot be used to determine the three-dimensional structure or conformation of IDDs due to the lack of rigidity. Likewise, NMR, while useful for understanding intramolecular spatial relativity, cannot provide an overall impression of the shape or structure of IDDs. Instead, other methods, such as small-angle X-ray scattering (SAXS), fluorescence spectroscopy, and circular dichroism (CD) can be used to characterize and monitor overall molecular shape, intramolecular interactions and positioning, and the presence and in-solution integrity of secondary structure (Schwalbe *et al.*, 2014). Furthermore, a host of other techniques have been developed and employed to characterize and study IDDs (Tomba, 2011).

Bioinformatic Platforms

The Protein Data Bank (PDB) is the definitive central repository for all protein structural data (Bernstein *et al.*, 1997). As of May 2014 there are ~100,000 individual structures deposited in the PDB. Because knowing the three-dimensional structure of proteins directly impacts our understanding of biological function and evolutionary mechanisms, a number of automated bioinformatic platforms can sort and classify this wealth of structural data. The general assumption employed by each of these databases focuses on identifying structural similarity and extending the evolution of individual domain structure to provide possible biological function (Hadley and Jones, 1999). In the following section, we summarize a number of databases and bioinformatic tools for classifying protein structures, inferring aspects of structural ancestry and evolution, and for predicting secondary and tertiary structure of proteins.

To understand the manner by which many of the bioinformatics databases classify protein domains, one must make distinctions between the levels of domain classification. Generally, protein domains can be described by class, fold, and superfamily (Hadley and Jones, 1999). The most general classification, class, refers to the secondary structure composition of the domain – for example, α -helical versus β -strand structures. Fold is a more specific term as it describes how the structural elements within a structural domain are connected and interact. The final classification is superfamily, which links three-dimensional fold with function. The latter classification is useful in evolutionary analysis, as proteins that share a three-dimensional fold and similar function are likely evolutionarily related. In addition, domains of high functional relatedness and high sequence identity are sometimes classified into families (Hadley and Jones, 1999). These classifications of domains provide for structural analysis and comparison using these databases.

The most utilized servers for domain classification and identification are the Structural Classification of Proteins (SCOP), the Class, Architecture, Topology, and Homologous superfamily (CATH), and Families of Structurally Similar Proteins (FSSP) databases (Hadley and Jones, 1999). The SCOP database (Murzin *et al.*, 1995) is a useful tool for understanding the contributions of different motifs on the structure of domains and multi-domain proteins. The SCOP database organizes proteins into five unique classes by fold

composition: (1) α proteins, whose structure is comprised of mostly α -helices; (2) β proteins, whose structure is comprised of mostly β -sheets; (3) α/β proteins, whose fold integrates both α -helices and β -strands; (4) $\alpha + \beta$ proteins, whose fold contains both α -helices and β -strands that are largely separated in the global domain or protein fold; and (5) multi-domain proteins, which may contain distinct domains from one or more than one of the four aforementioned classes. Additional classes of proteins, including membrane proteins, small proteins, designed proteins, and peptides, are also represented in this database.

In contrast to SCOP, the CATH database (Orengo *et al.*, 2002) employs automated computer comparisons to classify and identify protein domains. In essence, CATH generates a hierarchical structural lineage of a protein based on automated classification at the class level to further assign similarities in topology (or three-dimensional fold) and at the homologous superfamily level. The architecture level is assigned manually. Together, the hierarchically grouping of each queried protein sequence at each level allows for indexing and comparison to proteins of known fold and function. Overall, this database allows for comparison of fold and even evolutionary ancestry.

The FSSP database is also a fully automated platform that employs statistical Z-scores to compare structural homology (Holm and Sander, 1999). Unlike the SCOP and CATH databases, FSSP uses the Dali program to directly compare a queried structure to other structures in the PDB. Based on the Z-score, FSSP generates a ranking of three-dimensional similarity where a higher Z-score correlates to high structural homology. Matches with a Z-score less than two are considered to lack structural similarity. Comprehensive comparison of SCOP, CATH, and FSSP (Hadley and Jones, 1999; Getz *et al.*, 2002) reveals both inherent advantages and disadvantages of each individual platform.

Whereas these SCOP, CATH, and FSSP are important and powerful tools, implementing libraries of hidden Markov models (HMMs) in protein and nucleotide sequence analysis (Hughey and Krogh, 1996) allowed for improvement of domain identification and classification databases. For instance, the SUPERFAMILY database examines the evolutionary relationships of an individual protein fold or domain (Gough and Chothia, 2002; Wilson *et al.*, 2009). Users can subject a nucleotide or protein sequence to be grouped into SCOP superfamily classifications using a library of HMMs based on each of the SCOP superfamilies. SUPERFAMILY compares the queried sequence to HMMs of all proteins with a known structure and then allows comparison of the queried structure to all sequenced genomes to provide insight into the evolutionary lineage of domains. Overall, this level of analysis allows users to examine conservation of a domain regardless of the presence of amino acid sequence identity.

Additionally, implementing HMMs on multiple sequence alignments led to the development of databases like Simple Modular Architecture Research Tool (SMART; Letunic *et al.*, 2012; Schultz *et al.*, 1998) and Pfam (Finn *et al.*, 2014). Both databases are useful for domain identification and classification at the protein sequence level. Likewise, both the I-TASSER (Zhang, 2008) and Phyre2 (Kelley and Sternberg, 2009) servers provide similar services. Building upon previously mentioned databases, both I-TASSER and Phyre2 use

HMMs to classify proteins whose three-dimensional structures have not yet been elucidated. Both servers are also capable of generating homology models for use in understanding structure-function relationships, for informational purposes, or for use as search models for molecular replacement in X-ray crystallography.

Overall, the development of these bioinformatic resources enable structural, functional, and evolutionary analyses of many proteins without obtaining direct structural data. The value and power of these databases lies in the ease with which they generate new testable hypotheses.

Domains in Evolution: Modularity and Combinatorial Protein Structure

Development of biochemical, biophysical, and bioinformatic tools to identify and classify protein domains is a means of linking and understanding protein structure in the context of evolution. Another way of describing domains is as structural modules that lead to functional diversity in evolution (Moore *et al.*, 2008). The smallest proteins often possess only a single domain, although many proteins contain multiple domains. The fundamental idea that proteins evolved to have either repeated domains or multiple domains has been postulated for decades. Recent advances in bioinformatic resources, however, provide a clearer view of structural similarity and homology with functionality across genomes and over evolutionary timescales. This evidence, then, suggests evolution exploits the modularity of protein domains to create multi-domain proteins with more complex and functions.

Multi-domain protein families evolved to perform complex biochemical and cell signaling processes. A classic example of a multi-domain protein is pyruvate kinase, which catalyzes the conversion of phosphoenolpyruvate to pyruvate in glycolysis (Gupta and Bamezai, 2010). Pyruvate kinase contains three modular domains: an α/β -barrel domain, a β -barrel domain, and an $\alpha/\beta/\alpha$ -sandwich domain. These three domains work in concert to catalyze the transfer of a phosphate group from phosphoenolpyruvate to adenosine diphosphate (ADP) to generate pyruvate and adenosine triphosphate (ATP). Interestingly, this three-domain protein is retained throughout almost all organisms and the modular structure of the protein is also largely conserved.

Protein domains can also greatly expand the diversity of function through reorganization of functional modules in a combinatorial manner. For example, non-ribosomal peptide synthetases (NRPS) are large proteins that possess multiple enzymatic domains with each domain catalyzing a specialized reaction (Strieker *et al.*, 2010). These large proteins synthesize non-ribosomal peptides, which are often important natural products with antimicrobial or other qualities. Importantly, these proteins evolved as gene clusters that encode an ordered series of domains capable of performing intricate biosynthetic steps, including adenylation, cyclization, condensation, epimerization, methylation, and oxidation/reduction reactions for the synthesis of non-ribosomal peptides. Moreover, the diverse combination of NRPS domains directly results in chemical diversity in the resulting molecules.

The study of NRPS, as well as other multi-domain proteins, led to the idea that scientists can engineer multi-domain proteins to perform a custom biochemical process (Cane *et al.*, 1998). This science, often called combinatorial protein biochemistry or protein engineering, exploits the independent stability and modularity of protein domains to generate novel unnatural proteins by domain swapping. This engineering step has applications throughout many scientific fields including, but not limited to novel natural product biosynthesis, attenuation or perturbation of signaling cascades, and potentially the creation of proteins of novel function.

Conclusions

Proteins are the workhorses of the cells – they perform nearly all of the cellular processes that enable life. Central to their ability to manipulate biochemical processes, protein domains provide modular functionality to tailor macromolecular interactions, binding specificity, and chemistry. Advancements in elucidating the structures of domains, identifying domain functions, predicting domain boundaries, and inferring domain functionality, all contribute to improving our understanding of both protein function and evolution in cellular systems.

NMR in Structural and Cell Biology

G Marius Clore, National Institutes of Health, Bethesda, MD, USA

Published by Elsevier Inc.

Introduction

Nuclear magnetic resonance (NMR) is a powerful spectroscopic technique that permits the detailed study at atomic resolution of the three-dimensional structures and dynamics of macromolecules and their complexes in solution (Wüthrich, 1986; Clore and Gronenborn, 1989; Clore and Gronenborn, 1998a; Cavanagh *et al.*, 2007). The major source of structural information resides principally in a large number of short (<6 Å), approximate interproton distance restraints derived from nuclear Overhauser enhancement (NOE) measurements. These can be supplemented by torsion angle restraints derived from three-bond scalar couplings and backbone chemical shifts, orientational restraints in the form of residual dipolar couplings (RDCs) measured in weak alignment media, and long-range distance restraints (up to 35 Å) from paramagnetic relaxation enhancement (PRE) or paramagnetic pseudocontact shift (PCS) measurements. Dynamical information can be derived over a wide range of time scales ranging from picoseconds to seconds (Cavanagh *et al.*, 2007). Techniques include relaxation spectroscopy to measure dynamics of bond vectors in the picosecond to low nanosecond regime (faster than the rotational correlation time), relaxation dispersion spectroscopy in the microsecond to millisecond regime, RDCs potentially in the picosecond to millisecond regime, *z*-exchange spectroscopy for the millisecond to sub-second regime, and real time spectroscopy for the second regime upward. Recent interest in dynamics has largely focused on the application of relaxation dispersion spectroscopy to detect and characterize the kinetic properties of sparsely populated species (Korzhnev and Kay, 2008), PRE to detect and visualize such species (Clore *et al.*, 2007), and lifetime line broadening and dark-state exchange saturation transfer (DEST) spectroscopy to probe kinetics and dynamics of interactions of NMR visible molecules with large megadalton assemblies that are invisible to NMR (Fawzi *et al.*, 2011).

Brief Historical Perspective of NMR and Solution Structure Determination of Macromolecules

The development of two-dimensional ^1H -NMR spectroscopy (Ernst *et al.*, 1987) led to the first three-dimensional solution structure determinations of small proteins in the mid-1980s (Williamson *et al.*, 1985; Clore *et al.*, 1986). Subsequent work incorporating larger numbers of interproton distance and torsion angle restraints together with stereospecific assignments led to significant increase in both precision and accuracy (Clore and Gronenborn, 1998a,b; Clore *et al.*, 1986). Chemical shift overlap, however, limited the successful application of 2D ^1H -NMR techniques to proteins less than about 100 residues (~ 10 kDa). The late 1980s and early 1990s witnessed the development of 3D and 4D heteronuclear NMR spectroscopy which extended the range of applicability

of the NMR method to significantly larger systems (Clore and Gronenborn, 1991). The first structure determination of a protein larger than 150 residues using 3D and 4D NMR was interleukin- 1β (~ 18 kDa), which at the time was $\sim 50\%$ larger than any previous NMR protein structure determination (Clore *et al.*, 1991). Over the next few years, these methods were extended to a variety of protein-peptide and protein-DNA complexes (Clore and Gronenborn, 1998a). Hybrid approaches combining existing high-resolution structures determined either by crystallography or NMR with sparse experimental NMR data, solution X-ray scattering, and computational techniques involving the application of conjoined rigid body/torsion angle-simulated annealing saw the structure determination of a number of significantly larger protein-protein complexes and proteins (up to ~ 150 kDa) (Clore and Gronenborn, 1998a; Schwieters *et al.*, 2010). At the same time, deuteration combined with transverse relaxation optimized spectroscopy further increased the molecular weight range by significantly reducing linewidths (Peruvshin *et al.*, 1997; Kay, 2005). More recently, novel techniques, based on the application of PRE, have been developed to visualize sparsely populated, highly transient species that are undetectable by conventional biophysical and structural techniques, including crystallography, conventional NMR, cryoelectron microscopy, and single molecule spectroscopies (Clore *et al.*, 2007; Iwahara and Clore, 2006; Tang *et al.*, 2006, 2007; Clore and Iwahara, 2009).

Fundamentals of NMR Structure Determination

Macromolecular structure determination by NMR is intrinsically a highly specialized, labor-intensive and time-consuming technique. In addition, for a system of any reasonable size (say greater than about 70 residues) isotopic labeling with ^{15}N and ^{13}C is required. For even larger systems, additional labeling schemes are also necessary, including site specific isotope-labeling, deuteration and methyl protonation on a ^{13}C and ^2H background. Numerous reviews have been written on the subject detailing the experimental and computational methodologies involved (Wüthrich, 1986; Clore and Gronenborn, 1989, 1991, 1998a,b; Cavanagh *et al.*, 2007).

Determining the structure of a single protein by NMR can be broken down into essentially four steps: (1) sequential resonance assignment making use of a number of experiments to identify through-bond connectivities along the backbone and side chains (usually 3D triple resonance experiments); (2) assignment of cross-peaks in nuclear Overhauser enhancement spectra (usually 3D and 4D) to obtain short (≤ 6 Å) interproton distance restraints which provide the main source of geometrical information; (3) measurement of additional NMR observables that provide useful conformational information (these may include three-bond scalar couplings that are related to torsion angles by simple empirical equations; backbone

chemical shifts which are related empirically to backbone ϕ/ψ torsion angles; long-range orientational restraints, such as RDCs measured in dilute liquid crystalline media; and (4) calculation of the three-dimensional structure from the experimental NMR restraints using simulated annealing. Generally an iterative refinement strategy is employed (Clore and Gronenborn, 1989, 1991, 1998b): calculations are initially carried out with a limited set of interproton distance restraints corresponding to NOE cross-peaks with unambiguous assignments; further interproton distance restraints from the remaining NOE cross-peaks are subsequently added in an iterative manner on the basis of a successively calculated series of structures. While improvements in spectrometer technology (e.g., the advent of cryoprobe technology that increases the signal-to-noise ratio three- to fourfold; higher field magnets that increase spectral resolution, thereby reducing spectral overlap) has reduced the measurement time to some extent, collecting all the data necessary to solve an NMR structure at high accuracy may still require several months. Similarly, improvements in both spectral analysis software (Herrmann *et al.*, 2002a; Gerstein *et al.*, 2003; Yee *et al.*, 2003) and structure calculation algorithms (Schwieters and Clore, 2001; Linge *et al.*, 2003; Herrmann *et al.*, 2002b; Kuszewski *et al.*, 2004, 2008) has permitted the introduction of some degree of automation, but extensive human intervention is still necessary to fully and reliably interpret the data in all but the simplest of cases.

Place of NMR Spectroscopy in Structural and Cell Biology

In this light, what contribution can NMR make to structural and cell biology? There are two major methods for deriving high-resolution structural information at atomic resolution: NMR spectroscopy in solution and single crystal X-ray diffraction. In rare instances, cryoelectron microscopy is also capable of providing high-resolution information in the solid state. In addition, mass spectrometry in combination with cross-linking data is potentially capable of providing low-resolution structural information when combined with the computational techniques conventionally employed to derive structures from NMR data. If crystals can be rapidly obtained, there is little doubt that crystallography, particularly with the advent of synchrotron X-ray sources, offers the fastest route to high-resolution structure determination. However, complexes are generally more difficult to crystallize than isolated proteins, and it is usually the case that weak complexes (with K_D 's in the 1–100 μ M range) are extremely difficult to co-crystallize, while very weak complexes (K_D 's > 1 mM) are virtually impossible to crystallize. In the case of NMR, complexes are amenable to structural investigation providing exchange is either fast (weak binding) or slow (tight binding) on the chemical shift time scale. If exchange, however, is intermediate on the chemical shift time scale, the signals are broadened out precluding any detailed structural work.

A full structure determination of a protein–protein complex by NMR is extremely time consuming. For example, in the case of the 40 kDa EIN · HPr complex from the bacterial phosphotransferase system, the total NMR measurement time

alone was ~ 3500 h (or 4.8 months) (Garrett *et al.*, 1999). Clearly, therefore, the conventional approach is not suitable for high throughput. Fortunately, new developments have significantly shortened the amount of time required by making full use of prior knowledge in the form of existing high-resolution crystal or NMR structures of the free proteins (Schwieters and Clore, 2001; Clore, 2000; Clore and Bewley, 2002). Measurement of RDCs can quantitatively confirm that the structures of the components within the complex are either unchanged from that in the free-state or exhibit specific regions with identifiable structural changes. Similarly, chemical shift perturbations can also be used qualitatively in this regard since small chemical shift perturbations do not entail any significant structural changes. With this information in hand it is then possible to derive high-resolution structures of complexes using limited intermolecular NOE data to provide translation (as well as orientational) information and, if measurable, RDC data (Bax *et al.*, 2001; Prestegard *et al.*, 2000) to generate very accurate orientational information. In addition, strategies based on orientational information from RDCs have been developed whereby translational information from NOE data can be entirely replaced in suitable cases by highly ambiguous intermolecular distance restraints derived from $^{15}\text{N}/^1\text{H}_\text{N}$ chemical shift perturbation mapping (Clore and Schwieters, 2003). Long-range distance restraints from a paramagnetic label attached to an engineered surface cysteine on one partner to nuclei of the other partner can also be very helpful and can replace the measurement of intermolecular NOE data completely if multiple paramagnetic labels are used (Pintacuda *et al.*, 2007).

Experimental and Computational Considerations

Given that structure determination of proteins has been extensively reviewed, we will briefly review the main experimental restraints and computational techniques used in the structure determination of complexes.

Intermolecular Distance Restraints

As noted above, the NOE is the primary source of geometric information for NMR-based structure determination (Wüthrich, 1986; Clore and Gronenborn, 1989, 1998a,b). The NOE (in the initial rate approximation) is proportional to the sixth root of the distance between two protons. The upper limit for interproton distances that can be detected using the NOE is 5–6 Å. The key to deriving intermolecular NOE-derived interproton distance restraints lies in combining various isotope (^{15}N and ^{13}C)-labeling strategies with isotope-filtering experiments that permit one to detect NOEs on protons attached to specific isotopes of nitrogen and carbon (i.e., NMR active such as ^{15}N or ^{13}C , or NMR inactive such as ^{14}N and ^{12}C) (Clore and Gronenborn, 1998a). For example, in a complex comprising one protein labeled uniformly with ^{13}C and the other at natural isotopic abundance (i.e., ^{12}C), one can selectively detect NOEs from protons attached to ^{13}C to protons attached to ^{12}C .

Paramagnetic-Based Distance Restraints

It is possible to derive intermolecular distance restraints using another NMR-based approach which involves derivatizing (one at a time) suitable surface accessible cysteines (which may have to be introduced by site-directed mutagenesis) on one protein with either a nitroxide spin label or a metal-binding site (such as EDTA) and measuring the resulting PRE or PCS on the other protein to yield long-range (15–35 Å) distance restraints (Clore *et al.*, 2007; Pintacuda *et al.*, 2007). Because in most cases the paramagnetic label is attached to the protein by a linker involving several rotatable bonds, it is essential to consider the conformational space sampled by the paramagnetic label in order to obtain accurate results (Clore and Iwahara, 2009). Two types of measurement can be made with paramagnetic labels, depending on the nature of the label. For paramagnetic labels with an isotropic g -tensor (e.g. Mn^{2+} , Gd^{3+} , nitroxide radical), pseudocontact shifts (PCSs) are not observed and PRE measurements can be carried out to determine the PRE rates for each paramagnetic- ^1H interaction from the difference in relaxation rates (usually transverse) between the paramagnetic and diamagnetic samples. When the g -tensor is anisotropic (e.g., many lanthanide ions), PCSs are observed.

Both PRE and PCS effects arise from the dipole-dipole interaction between the unpaired electron of the paramagnetic spin and a nuclear spin. Because of the large magnetic moment of the electron these effects are very large and measurable over much larger distances (up to 35 Å in suitable cases) than the dipolar interaction between two protons that gives rise to the NOE. The magnitude of the PRE is related to the sixth root of the distance between the paramagnetic center and a proton and can be directly used in refinement. The PCS has the same functional form as RDCs and is dependent on both the cube root of the distance between the paramagnetic center and the nuclei of interest and the orientation that the paramagnetic center-nucleus vector makes relative to the χ paramagnetic tensor.

In general, paramagnetic effects arising from an extrinsic paramagnetic center (as opposed to one that is intrinsic as is the case for metalloproteins) can only be applied in a rational manner if one already has a good idea of the interaction surfaces involved in complex formation. Such information can be derived rather easily by either $^{15}\text{N}/^1\text{H}_\text{N}$ chemical shift perturbation mapping (Walters *et al.*, 2001) or cross-saturation experiments (Takahashi *et al.*, 2000). The latter experiment is far more challenging experimentally since it necessitates that one of the protein is not only ^{15}N -labeled but fully deuterated as well.

Paramagnetic effects, however, do have to be used with some caution. In the case of very tightly binding complexes where exchange is slow on the paramagnetic relaxation time scale, the paramagnetic effects will arise solely from the specific complex (Clore *et al.*, 2007; Clore and Iwahara, 2009). However, when exchange is fast, the footprints from paramagnetic effects arising from minor species and configurations are apparent. This is more marked for PRE measurements than PCS ones owing to the respective sixth versus cube root distance dependencies. It is precisely these effects that have permitted states that are undetectable by conventional structural and biophysical techniques to be studied.

Other Sources of Distance Information

NMR is not the only method that can be used to derive intermolecular distance restraints. It is also possible to derive distance restraints using a combination of cross-linking, proteolytic digestion, and mass spectrometry (Bennett *et al.*, 2000; Sinz and Wang, 2001; Schulz *et al.*, 2004). In many cases, however, the data will not yield unique cross-linking partners but multiple possibilities.

Fluorescence energy transfer (FRET) through non-radiative dipolar-dipolar coupling from the fluorophore, the energy donor, to a second chromophore, the energy acceptor, scales as the sixth root of the distance between the two chromophores and can probe separations ranging from 10 to 100 Å (Hillisch *et al.*, 2001). Likewise double nitroxide spin-labeling coupled with pulsed electron paramagnetic resonance (EPR) methods such as double electron-electron resonance (DEER) based on the magnitude of the magnetic dipolar coupling of the unpaired nitroxide electrons which scales as the cube root of the separation between the two nitroxide labels, can yield remarkably accurate distances in the 20–60 Å range (Altenbach *et al.*, 2008). FRET and EPR are not limited by the molecular weight of the system being studied, but suffer from a major drawback in so far that only a single pairwise distance can be measured per sample (i.e., each distance requires a new double spin-labeled or double chromophore labeled sample, with the labels in different positions). Thus, although FRET and EPR can yield very specific information they do not afford a practical approach for solving three-dimensional structures of proteins or their complexes.

Orientational Restraints

Long-range orientational restraints can be derived from the measurement of RDCs (Bax *et al.*, 2001; Prestegard *et al.*, 2000) and chemical shift anisotropy (Wu *et al.*, 2001; Tjandra *et al.*, 1997) in liquid crystalline media, and in suitable cases from heteronuclear T_1/T_2 data (Tjandra *et al.*, 1997). The characteristic feature of these various parameters is that they yield direct geometric information on the orientation of an interatomic vector(s) with respect to an external axis system (e.g., the alignment tensor in liquid crystalline media, the diffusion tensor for relaxation measurements) expressed in terms of two angles: θ , the angle between the interatomic vector and the z axis of the tensor, and ϕ , the angle which describes the position of the projection of the interatomic vector on the x - y plane of the tensor.

For most practical purposes, RDCs provide the easiest method for deriving orientational information. In an isotropic medium, the dipolar couplings average to zero. In the solid state, the maximum value of the ^{15}N - ^1H dipolar coupling is 20.7 kHz. To effectively measure dipolar couplings in solution, therefore, it is necessary to devise means of inducing only a small ($\sim 10^{-3}$) degree of order such that the ^{15}N - ^1H dipolar couplings lie in the ± 20 Hz range. Experimentally, this is achieved by dissolving the protein or protein complex of interest in a dilute, water soluble, liquid crystalline medium. Examples of such media include lipid bicelles, filamentous phages such as fd or pf1, rod-shaped viruses such as tobacco mosaic virus, polyethylene glycol/hexanol, and stretched polyacrylamide gels.

Some Computational Methods

In many instances, protein complex formation involves no significant changes in backbone conformation. Thus, if the structures of the individual proteins are already known at high resolution and it can be shown that the backbone conformation remains essentially unchanged upon complex formation (e.g., by comparison of dipolar coupling data measured on the complex with the X-ray structures of the free proteins), one can then make use of conjoined rigid body/torsion angle dynamics to rapidly solve the structure of the complex on the basis of intermolecular NOE data and backbone NH dipolar couplings (Schwieters and Clore, 2001; Clore, 2000). In this procedure, only the interfacial side chains are allowed to alter their conformation. The backbone and non-interfacial side chains of one protein are held fixed, while those of the second protein are only allowed to rotate and translate as a rigid body. This has been applied with considerable success in the case of the 30–70 kDa protein–protein complexes of the bacterial phosphotransferase system (Clore and Venditti, 2013), as well as to the 42 kDa ternary Oct1 · Sox2 · Hoxb1-DNA ternary transcription factor complex (Williams *et al.*, 2004).

It should be emphasized that conjoined rigid body/torsion angle dynamics can readily be extended to cases where significant changes in backbone conformation are localized to specific regions of the protein, such as the binding interface. In such cases, both the interfacial side chains and the relevant portions of the protein backbone would be given torsional degrees of freedom, and the experimental data would also have to include intramolecular NMR restraints (NOE, dipolar coupling, etc.) relating to that portion of the backbone. This, for example, is the strategy that was employed to solve the structure of the IIA^{Mtl} · HPr complex (Cornilescu *et al.*, 2002). This was necessitated because the crystal structure of IIA^{Mtl} (Van Montfort *et al.*, 1998) which contains multiple copies of IIA^{Mtl} in the unit cell, revealed alternate conformations for four loops in relatively close proximity to the putative interaction surface with HPr.

Providing the complex under study can be aligned in a suitable liquid crystalline medium, the measurement of dipolar couplings is straightforward and permits one to determine the relative orientation of two proteins in a complex. Dipolar couplings, however, do not yield any translational information which is essential for docking. Clearly, NOE-derived intermolecular interproton distance restraints provide the most useful and reliable source of translational information. However, intermolecular NOEs are not always easy to observe and their unambiguous assignment is still difficult and time consuming, particularly for larger complexes. Backbone ¹H_N and ¹⁵N chemical shifts, on the other hand, are highly sensitive to environment and have been extensively used to rapidly map interaction surfaces on proteins (Walters *et al.*, 2001). Not surprisingly, examination of the NMR literature reveals hundreds of examples of chemical shift mapping studies; to date, however, only a handful of structures of macromolecular complexes have been determined by NMR. Recently, it has been shown that it is possible to convert chemical shift perturbation maps into highly ambiguous intermolecular distance restraints which, in combination with orientational restraints from dipolar couplings, can reliably

and accurately dock the partner proteins in a complex by means of rigid body/torsion angle dynamics calculations (Clore and Schwieters, 2003). Clearly, this methodology provides a powerful tool for high throughput structural proteomics and, moreover, can greatly accelerate the determination of higher accuracy NMR structures of complexes (including the detailed placement of interfacial side chains) by providing a good starting point for the assignment of intermolecular NOE data.

Structural Proteomics of the Bacterial Phosphotransferase System

In bacteria, carbohydrate transport across the membrane is mediated by the phosphoenolpyruvate:sugar phosphotransferase system (PTS) which provides tight coupling of translocation and phosphorylation (Deutscher *et al.*, 2006). The PTS is a classical example of a signal transduction pathway involving phosphoryl transfer whereby a phosphoryl group originating on phosphoenolpyruvate is transferred to the translocated carbohydrate via a series of bimolecular protein–protein complexes. The first two steps of the PTS are common to all sugars: enzyme I (EI) is autophosphorylated by phosphoenolpyruvate and subsequently donates the phosphoryl group to the histidine phosphocarrier protein HPr. The proteins downstream from HPr comprise the sugar-specific enzymes II which fall into four distinct families: glucose (Glc), mannitol (Mtl), mannose (Man) and lactose/chitobiose (Chb). Although the four families bear no sequence or structural similarity, they do possess similar organizations consisting of two cytoplasmic domains A and B, and one or two membrane-bound domains, C and D, which may or may not be covalently linked to one another. The active site residue of the A domains is always a histidine which accepts the phosphoryl group from HPr on its Nε2 atom and donates a phosphoryl group to either a cysteine residue (in the case of IIB^{Glc}, IIB^{Mtl} and IIB^{Chb}) or to the Nδ1 atom of a histidine residue (in the case of IIB^{Man}). Subsequently the phosphoryl group is transferred onto the incoming sugar on the cytoplasmic side of the membrane-bound C domain (also known as the sugar permease).

The complexes in this pathway are rather weak with *K_D*'s ranging from 1 μM to 3–6 mM. The *K_D*'s in the millimolar range relate to complexes involving isolated domains that are connected by 20–30 residue long flexible linkers in the intact protein (Clore and Venditti, 2013). Although binding in such instances is very weak, it is in fact perfectly tuned to the system. In particularly, it can readily be calculated, based on the expected average end-to-end distance for the linkers, that these millimolar equilibrium dissociation constants correspond to 50–85% probabilities of the two linked domains interacting with one another at any given time. Although high-resolution crystal structures and NMR structures have been determined for many of the individual proteins of the PTS, crystallization of these protein–protein complexes has proven to be refractory, despite many years of trying. Thus, this system provides a showcase for the impact of NMR in structural proteomics.

Figure 1 shows ribbon diagrams of structures of all nine cytoplasmic PTS complexes solved in our laboratory

Figure 1 Structural biology of the bacterial phosphotransferase signal transduction pathway. (a) Diagrammatic representation of the pathway. The first two steps are common to all branches, and thereafter the pathway splits into four sugar-specific branches (glucose, mannitol, mannose, and lactose/chitobiose). (b) Ribbon diagrams of the nine protein-protein complexes of the *Escherichia coli* phosphotransferase system.

(Clore and Venditti, 2013). These complexes shed light on understanding fundamental aspects of protein-protein recognition, mechanisms for phosphoryl transfer between proteins, and the diversity of structural elements recognized by a single protein. Specificity of the protein-protein interaction surfaces is characterized by geometric and chemical complementarity, coupled with extensive redundancy to permit the effective recognition of multiple partners. There is little or no conformational change in the protein backbone before and after association. Some interfacial side chains, however, adopt different conformations (side chain conformational plasticity)

depending on the interacting partner so as to achieve optimal intermolecular interactions. A consequence of these properties is increased velocity in signal transduction by eliminating any unnecessary time delay required for significant conformational change.

The interaction surfaces for HPr on enzyme I and the four sugar-specific enzymes IIA are very similar despite the fact that their underlying structures are completely different in terms of linear sequence, secondary structure and topological arrangement of structural elements. HPr makes use of essentially the same surface to interact with both its upstream and

downstream partners (cf. [Figure 1](#)). Concomitantly, the binding sites for the sugar-specific enzymes IIB and HPr on the corresponding sugar-specific enzymes IIA overlap extensively. One might therefore anticipate that the enzymes IIB could also interact with EIN. However, NMR data indicate that there is absolutely no interaction between EIN and any of the sugar-specific enzymes IIB at millimolar concentrations. From a functional perspective this is important since it ensures that the PTS cascade is not bypassed. In addition, prevention of any potential shortcuts circumventing HPr and the sugar-specific enzymes IIA is also necessary since these proteins in different states of phosphorylation also regulate the functions of proteins in other pathways ([Deutscher et al., 2006](#)). The structural basis for specificity and discrimination lies in the different charge distributions on the interaction surfaces of HPr and the sugar-specific enzymes IIB such that binding of a sugar-specific enzyme IIB to EIN is precluded by electrostatic repulsion ([Clore and Venditti, 2013](#)).

Exploring Sparsely Populated States of Proteins and Their Complexes

Many biological processes proceed via sparsely populated species. Examples include the initial formation of encounter complexes in macromolecular association, target searching in specific protein–DNA recognition, conformational selection in ligand binding, conformational transitions associated with allostery, intermediates along the protein folding pathway or in the course of enzyme catalysis, and early events in self-assembly processes. In general the populations of these states at equilibrium are low and their lifetimes are short. Consequently, transient states arising from rare but rapid excursions between the global free energy minimum and higher free energy local minima are extremely challenging to study at atomic resolution under equilibrium conditions since they are effectively invisible to most structural and biophysical techniques including crystallography, conventional NMR spectroscopy, electron microscopy and single molecule spectroscopy. Recent developments in NMR have rendered short-lived, sparsely populated states accessible to spectroscopic analysis, yielding considerable insights into their kinetics, thermodynamics, and structures.

Principal NMR Methods to Probe Transient Sparsely Populated States

Three main NMR methods have been developed over the last few years to probe rare invisible states of macromolecules and their complexes at equilibrium: namely PRE, relaxation dispersion spectroscopy and lifetime line broadening coupled with DEST spectroscopy (see [Anthis and Clore \(2015\)](#) for a recent in-depth review).

The PRE requires that the distances between a paramagnetic label and the monitored spins (usually protons) are significantly shorter in the sparsely populated state than in the major species, and that the lifetime of the minor species is less than $\sim 250\text{--}500\ \mu\text{s}$ ([Iwahara and Clore, 2006](#); [Tang et al., 2006, 2007](#); [Clore and Iwahara, 2009](#)). In this exchange regime, the footprint of sparsely populated states can be observed on PRE

profiles measured on the resonances of the major species, thereby yielding structural information that is directly related to paramagnetic center–nuclei distances, from which it is possible, under suitable circumstances, to compute a structure or ensemble of structures for the minor species ([Tang et al., 2006, 2007](#)). Relaxation dispersion spectroscopy is dependent on the existence of significant chemical shift differences between the NMR active nuclei (^1H , ^{15}N or ^{13}C) in the various states, and in general can be used to probe events occurring on time scales ranging from about $50\ \mu\text{s}$ to $10\ \text{ms}$ ([Korzhnev and Kay, 2008](#); [Palmer et al., 2001](#); [Loria et al., 2008](#); [Baldwin and Kay, 2009](#)). Lastly, lifetime line broadening and DEST probe exchange dynamics at atomic resolution between NMR visible molecules and large (in excess of $1\ \text{MDa}$) NMR invisible ‘dark’ states on time scales ranging from $0.5\ \text{ms}$ to $1\ \text{s}$ ([Fawzi et al., 2011, 2014](#); [Libich et al., 2013](#)). The DEST experiment relies entirely on large differences in transverse relaxation rates between the NMR visible and invisible species. These three complementary techniques are capable of detecting states with populations as low as 0.5% .

Basis of PRE for the Study of Sparsely Populated States

The PRE yields structural information directly but cannot be used to obtain kinetic information (i.e., rate constants). The underlying theory of the PRE for static systems dates back to the late 1950s ([Solomon, 1955](#); [Bloembergen and Morgan, 1961](#)) and the PRE has long been used in the study of paramagnetic metalloproteins. The potential of the PRE for structure determination of single proteins, however, was first demonstrated in the mid-1980s ([Kosen, 1989](#)) but then largely neglected until about 10 years ago with the advent of straightforward biochemical methods for introducing paramagnetic labels at specific sites in proteins ([Battiste and Wagner, 2000](#)). Moreover, the quantitative use of the PRE for structure determination was thwarted until the introduction of the appropriate theoretical framework and computational methods to take into account the large conformational space sampled by a paramagnetic label attached to the protein via a linker with multiple rotatable bonds ([Iwahara et al., 2004](#)). By representing the paramagnetic label by an ensemble of states and taking care to calculate PRE order parameters from the coordinates during the course of structure refinement, it is possible to directly refine against the PRE relaxation rates and obtain accurate structures where agreement between the model and the experimental data is quantitatively assessed by a Q-factor analogous to a crystallographic R-factor ([Iwahara et al., 2004](#)).

The key insight into using the PRE to detect transient low-population species lies in rapid exchange phenomena whereby the transverse PRE observed on a major species is modulated by the presence of the minor species ([Iwahara and Clore, 2006](#)). In a two-site exchange system comprising two species A and B that interconvert on a time scale that is fast on the PRE time scale, the observed PRE measured on either resonance will be the population weighted average of the PRE rates for the two species. Thus, if one has, for example, a system where a particular paramagnetic center–proton distance is $30\ \text{\AA}$ for the major species and $8\ \text{\AA}$ for the minor species, the corresponding PRE rates (for a system $\sim 30\ \text{kDa}$ in size with Mn^{2+} as the

paramagnetic center) will have values of $\sim 2 \text{ s}^{-1}$ and $\sim 5600 \text{ s}^{-1}$, respectively. If the major and minor species are populated at 99% and 1%, respectively, the minor species will be invisible in the NMR spectrum. But in the fast exchange limit the observed PRE measured on the resonance of the major, NMR visible, species will be the population weighted average of the PREs for the major and minor species, in this instance $\sim 50 \text{ s}^{-1}$, much larger than that expected for the major species alone. Therefore, providing distances between the paramagnetic center and the protons of interest are significantly shorter in the minor species than the major one, and the interconversion rate between the two species is fast, the PRE profiles observed on the major species will reveal the footprint of the minor species. The PRE profiles can be analyzed quantitatively to derive structural information if the PRE profile for the major species is either known or can be calculated from a known structure (Tang *et al.*, 2006, 2007; Clore and Iwahara, 2009). As the exchange rate decreases, the influence of the minor species on the observed PRE profile for the major species will be reduced until in the slow exchange limit the PRE profile for the major species will be unaffected by the presence of the minor species. Thus, the use of the PRE to detect and characterize sparsely populated states is limited to rapidly exchanging systems, typically with lifetimes less than about 250–500 μs (Clore and Iwahara, 2009).

Basis of Relaxation Dispersion Spectroscopy

In an exchanging system between multiple states, the transverse relaxation rate (R_2) is given by the sum of the intrinsic transverse relaxation rate R_2^0 and an exchange contribution R_{ex} . The R_{ex} term is a function of the exchange rate k_{ex} (which in the case of a two-site exchange system is simply the sum of the forward and backward rate constants) and the chemical shift difference for the nucleus in the two distinct chemical environments. In the slow exchange regime, when k_{ex} is much (20-fold or more) smaller than the chemical shift difference measured in radians s^{-1} , two distinct resonances will be observed. In the fast exchange regime when k_{ex} is much (≥ 20) larger than the chemical shift difference, a single resonance will be observed at a position corresponding to the population weighted mean of the chemical shifts in the two states. In the extreme fast and slow exchange limits, the exchange contribution to the linewidth is negligible. In the intermediate regime, however, the R_{ex} term results in line broadening which is most marked when k_{ex} is equal to the chemical shift difference. Under these conditions, even the presence of a state populated at the 0.5% level can cause significant line broadening of the resonances of the major species. The key to relaxation dispersion spectroscopy lies in the use of special pulse sequences to progressively attenuate the R_{ex} contribution to the measured R_2 rate which can be achieved by applying a train of refocusing pulses while magnetization evolves under the influence of a chemical shift that varies stochastically as a result of the exchange process (Palmer *et al.*, 2001; Loria *et al.*, 2008; Baldwin and Kay, 2009). Because each nucleus follows a slightly different trajectory, dephasing of magnetization occurs resulting in larger R_{ex} rates and hence broader linewidths. By reducing the interval between the refocusing pulses (i.e. increasing the number of pulses during a fixed period T), dephasing is

decreased, the R_{ex} term is reduced and the linewidths become narrower. Plots of the observed R_2 rate as a function of the interval between the refocusing pulses yields what is known as a relaxation dispersion curve with large observed R_2 rates at low repetition rates and small R_2 rates at high repetition rates. The detailed shape of the relaxation dispersion curve is a complex function of the exchange rate k_{ex} , the populations of the states, the chemical shift difference between the states and the repetition rate. For data recorded at a single magnetic field, the contribution of population and chemical shift difference to R_{ex} cannot be separated *a priori*. Thus, unless the population of the species or the chemical shift difference between these species is already known, deconvolution of these two terms necessitates recording relaxation dispersion data at different magnetic field strengths since the species populations are independent of magnetic field while the chemical shift difference in frequency units is linearly proportional to the magnetic field. Typically relaxation dispersion experiments using refocusing pulses can probe exchange processes with lifetimes ranging from $\sim 50 \mu\text{s}$ to $\sim 10 \text{ ms}$ and occupancies for the minor species as low as 0.5–1%.

The key feature of NMR that distinguishes it from all other forms of spectroscopy is that interactions involving many sites of known identity can be probed simultaneously. The sites comprise NMR observable nuclei (^1H , ^{15}N , ^{13}C) whose resonance assignments in the major species are readily obtained using modern triple resonance NMR spectroscopy. Using global fitting procedures in which all the relaxation dispersion data at the observed sites are fitted simultaneously, it is possible to dissect kinetic pathways. The most commonly employed nucleus for relaxation dispersion experiments is the ^{15}N of the backbone amide groups. Yet, the structural information provided by ^{15}N chemical shifts alone is generally quite limited unless reference ^{15}N chemical shifts are already available for the various states being studied. More recent developments have extended relaxation dispersion measurements to all ^1H , ^{13}C and ^{15}N backbone atoms, as well as to side chain methyl groups (Sekhar and Kay, 2013). This opens the way to obtain highly reliable backbone ϕ/ψ torsion angle restraints for minor states derived from complete backbone chemical shifts, and even to compute 3D structures under suitable circumstances, thereby providing a potential avenue for obtaining full 3D structural information on sparsely populated states. More recent developments have shown that one can use relaxation dispersion experiments to obtain bond vector orientation information on minor states (Vallurupalli *et al.*, 2007). Two NMR observables are available, RDCs and residual chemical shift anisotropy (RCSA). Both involve the use of weakly aligned media (such as dilute solutions of bicelles and filamentous phages) to reintroduce anisotropic magnetic interactions that are otherwise averaged to zero in isotropic solution. Because these effects are small, highly accurate relaxation dispersion measurements are required and the experiments are extremely demanding.

Basis of Lifetime Line Broadening and DEST

Exchange dynamics between molecules free in solution and bound to the surface of a large supramolecular structure, a polymer, a membrane or solid support are important in many

phenomena in biology and material science. These interactions can be probed by lifetime line broadening and DEST spectroscopy to probe exchange dynamics at atomic resolution between NMR visible molecules and large (in excess of 1 MDa) NMR invisible 'dark' states on time scales ranging from 0.5 ms to 1 s (Fawzi *et al.*, 2010, 2011, 2014; Libich *et al.*, 2013).

Exchange line broadening can arise from either differences in chemical shifts (chemical exchange line broadening) or transverse relaxation rates (lifetime line broadening) between the free and bound states. When a molecule binds to a high (> 700 kDa) molecular weight entity, the reduced rate of molecular tumbling leads to a marked increase in transverse (R_2) relaxation rates (i.e., severe line broadening) which precludes direct observation of the bound state by standard NMR techniques. If the dissociation rate constant k_{off} is considerably smaller (by two orders of magnitude or more) than the R_2 in the bound state, the difference in R_2 values (ΔR_2) for the NMR visible species in the presence and absence of the large molecular weight species will be equal to the pseudo-first order association rate constant (Fawzi *et al.*, 2010, 2011). If k_{off} is comparable to or larger than R_2 in the bound state, ΔR_2 will be dependent upon both the association and dissociation rate constants as well as the R_2 in the bound state (Libich *et al.*, 2013).

The essence of the DEST experiment is that the large R_2 values in the bound state that preclude direct observation by NMR allow for efficient partial saturation of longitudinal magnetization of bound state resonances by a weak radio-frequency field, even at offsets where the magnetization of the free species is completely unaffected (Fawzi *et al.*, 2011). In other words, even though the bound resonances are completely broadened out beyond detection (i.e. they effectively lie in the baseline) they can be perturbed and partially saturated. Saturation of the bound resonances is then transferred back to the corresponding resonances of the free species by chemical exchange and subsequently measured as attenuation of the easily observed resonances of the NMR visible species. Operationally, the DEST experiment involves the creation of an action profile by applying weak saturation at set intervals from say + 35 kHz to - 35 kHz, and measuring the cross-peak intensities in a 2D-correlation spectrum as a function of the frequency offset of the saturation pulse. The resulting profiles are dependent upon the association and dissociation rate constants, and the transverse relaxation rates in the bound state.

Relevance to Cell Biology

The PRE has been used to study how the opposing constraints of speed and specificity are optimized in biological interactions. Examples include the first direct demonstration of intra- and intermolecular translocation of transcription factors to enhance specific site searching (Iwahara and Clore, 2006); the first experimental visualization of encounter complexes in protein-protein association (Tang *et al.*, 2006); the elucidation of conformational selection of a very low-population of correctly configured dimer in auto-processing of the HIV-1 protease precursor monomer (Tang *et al.*, 2008), a phenomenon of fundamental practical importance in the design of novel HIV protease inhibitors; and the dissection of the

complementary interplay between conformational selection and induced fit, exemplified by the characterization of a transient open-to-closed transitions in apo maltose binding protein (Tang *et al.*, 2007) and calmodulin that facilitate ligand-induced formation of the holo state (Anthis *et al.*, 2011).

Relaxation dispersion has shed fundamental insights into a range of biological problems of considerable significance (Korzhnev and Kay, 2008; Palmer *et al.*, 2001; Loria *et al.*, 2008; Baldwin and Kay, 2009; Sekhar and Kay, 2013). In the case of protein folding, this includes the structure determination of folding intermediates, the elucidation of the kinetics of their interconversion and the delineation of on- and off-pathway events. Relaxation dispersion has also been used to probe allosteric mechanisms associated with ligand binding in very large assemblies including chaperones, aspartate transcarbamoylase and the proteasome.

Lastly, lifetime line broadening and DEST have been used to probe exchange processes between monomer and protofibril-bound states of amyloid β (Fawzi *et al.*, 2010, 2011, 2014) and between intrinsically disordered proteins and the chaperonin GroEL (Libich *et al.*, 2013) on time scales of 0.5–100 ms, imprinting the residue-by-residue footprint of the NMR invisible protofibril-bound and GroEL-bound states on the easily observed monomer. The experiments on amyloid β shed light on protofibril formation, the structure and dynamics of protofibrils and exchange processes occurring on the surface and ends of protofibrils, which are of interest since the accumulation of toxic, aggregated forms of amyloid β are implicated in the etiology of Alzheimer's disease. The experiments on the interaction of intrinsically disordered proteins with GroEL unveil the complex molecular recognition process whereby GroEL recognizes a large array of sequences and structures. The demonstrated ability of the DEST technique to examine dynamics at single residue resolution of otherwise NMR invisible 'dark' states has the potential to revolutionize many areas of current interest in both biology and materials science.

Glossary

Amyloid Fibrous protein aggregates in which unfolded or misfolded polypeptides assemble to form an extended β -sheet structure. Amyloid accumulation is associated with a number of human pathologies.

Capture radius Greatest distance at which a protein can meaningfully interact with ('capture') its cognate ligand. Intrinsically unstructured proteins are thought to have a larger capture radius compared to structured proteins because they can occupy extended conformations.

Clathrate An ice-like water cage that surrounds solvent-exposed hydrophobic groups. Clathrate waters are less mobile than waters in bulk solvent; consequently, clathrate formation is entropically unfavorable. Their formation is enthalpically favored as their structure provides space for a hydrophobic solute while minimizing unsatisfied solvent H-bonding. See hydrophobic effect.

Coupled folding and binding Folding of an intrinsically unstructured protein into a well-defined conformation upon binding to a ligand. Coupled folding and binding is a common theme for intrinsically unstructured proteins.

Denatured State A heterogeneous ensemble of extended conformations occupied by a polypeptide; in most contexts, denatured state is synonymous with unfolded state. Compared to the native state, the denatured state is often nonfunctional, susceptible to proteolysis, and prone to aggregation.

Domain swapping The exchange of structural elements (e.g., a β -strand) between two independently folding domains. Often, domain swapping recapitulates the native 3° structure of the participating domains by swapping equivalent structural elements – but does so with nonnative connectivities. Domain swapping can be a form of protein misfolding.

Energy landscape A molecular analogy to the topographic map, the energy landscape is a plot of energy (e.g., Gibbs energy) as a function of molecular conformation. Although the energy landscape is frequently stylized as a three-dimensional surface, the folding reaction of even a simple 50 residue protein has hundreds of degrees of freedom.

Folding The conformational transition from the denatured state to the native state.

Folding frustration Formation of nonnative conformations with relatively low energy that kinetically block further productive folding.

Folding funnel The hypothesized shape of the folding energy landscape. A funneled energy landscape will efficiently guide a folding protein to the native conformation, proposed to be the energetic minimum, without needing to sample all possible conformations.

Folding mechanism The general features of folding that are shared by many proteins (e.g., nucleation followed by extension of native structure).

Folding nucleus The specific region of the polypeptide that initiates the folding reaction and templates the extension of native-like structure to adjacent sites.

Folding pathway The specific details of the folding reaction (e.g., which turn forms first). The folding pathway is sensitive to both the global architecture and the sequence of the protein under consideration.

Folding transition state The highest energy conformation, and therefore the highest energy barrier, along the folding trajectory. The energy of the folding transition state is related to the rate of folding, with higher energies resulting in slower folding processes.

Hydrophobic effect The propensity for hydrophobic substances to be excluded from aqueous solvent and coalesce (to minimize the hydrophobe–water interface). The hydrophobic effect is entropically driven by solvent properties; see clathrate.

Intrinsically unstructured proteins Proteins that do not adopt a well-defined ensemble of compact conformations.

Native state A homogeneous and limited ensemble of compact conformations adopted by a protein. The native state is often capable of specific chemical or biological function.

Roughness (of energy landscape) A measure of the number of conformational 'traps' that exist along the folding pathway.

Salt bridge An attractive interaction between positively and negatively charged amino acids comprised of both a charge interaction and hydrogen bonding. It is generally considered to be the strongest type of non-covalent interaction stabilizing protein structure.

Folding

General Principles

Proteins (polypeptides) are one of the three principle linear, unbranched biopolymers that define living systems, along with polyribonucleic acid (RNA) and polydeoxyribonucleic acid (DNA). Although all three classes of biopolymers are rich

in chemical information, it is proteins that serve as the key structural components, molecular machines, and catalysts that enable complex metabolism. Proteins are unique compared to other biopolymers because they must often 'fold' into a precise ensemble of closely related conformations, the 'native state,' to be functionally active. The structure of the native state is predominantly defined by the amino acid sequence of the protein, but can be modulated by environmental factors (e.g.,

temperature, pH, ionic strength, ligand concentration, voltage across a membrane, or mechanical stress) with functional consequences. To date, an analytical understanding of how amino acid sequence and chemical environment shape the native state structure remains elusive, though many general principles of protein structure and folding are known.

Protein Stability, A Delicate Balance between Enthalpy and Entropy

To a first approximation, the folding of a protein can be viewed as a transition between two thermodynamic states: the native state (an ensemble of closely related, compact conformations) and the 'denatured state' (a heterogeneous ensemble of extended, flexible conformations). The native state is most often associated with biological function whereas the denatured state tends to be nonfunctional, susceptible to degradation by proteases, and prone to aggregation. The overall stability of a protein – that is, the energetic difference between the native state and the denatured state – can be thought of as a 'tug of war' between various entropic and enthalpic considerations that favor one state over the other. In general, the native state is only marginally more stable than the denatured state, with an energy gap between the two states equivalent in magnitude to only a few hydrogen bonds.

The flexibility of the denatured state is a direct consequence of the molecular structure of the protein backbone, which traces the covalent bonds that 'string together' amino acids to form a polypeptide. For each peptide bond (the chemical link between amino acids) two freely-rotatable, single bonds are present in the protein backbone. In the denatured state, rotation about these single bonds is unimpeded and a vast number of conformations can be sampled. Upon folding, the conformational freedom of the backbone is constrained by the reinforcing intramolecular interactions that comprise the native state. Thus, from the perspective of the polypeptide chain, collapse into the native state structure is accompanied by a dramatic 'loss of entropy' (an unfavorable transition).

The native state and the denatured state make fundamentally different interactions with the surrounding solvent (water molecules) and, as a consequence, solvent structure must be considered to understand protein stability and folding. In the denatured state, nearly all residues – including both hydrophilic and hydrophobic side-chains – are solvent-exposed; thus, hydrogen bond donors and acceptors that reside on the protein backbone and side-chains are satisfied by water. The hydrophobic moieties of a denatured protein, however, are unable to form hydrogen bonds and, instead, induce a structural transition in the adjacent water molecules. To avoid the loss of a hydrogen bond (an unfavorable loss of enthalpy) water molecules form an ice-like cage, referred to as a 'clathrate,' around the hydrophobic group. The clathrate structure, however, is itself a trade-off by maximizing the number of hydrogen bonding partners, clathrate waters suffer a substantial loss of translational and rotational freedom (an unfavorable loss of entropy). The formation of clathrates is the basis of the 'hydrophobic effect' and is a major driving force for protein folding.

Upon folding into the native structure, the hydrophobic residues that were exposed to solvent in the denatured state are

buried into a solvent-excluded core, thereby releasing the clathrate waters. In addition, the hydrogen bonding of backbone donors and acceptors becomes largely self-satisfied by the native state structure, which serves as the basis for the commonly observed types of protein 2° structure (e.g., α -helix or β -strand). Thus, a large number of the waters that were H-bonded to polar groups in the denatured state are released when the protein adopts the native state structure. Taken together, collapse into the native state, from the perspective of the solvent, is accompanied by a dramatic 'gain of entropy' (a favorable transition).

In addition to the entropic benefit of sequestering hydrophobic residues into a solvent-excluded core, protein core formation is associated with favorable London dispersion forces, resulting in an enthalpic contribution to folding. To maximize the enthalpy of packing, protein cores often exhibit features of structural complementarity with minimal packing defects, resembling a sort of three-dimensional jigsaw puzzle. Other enthalpic contributions that favor folding result from 'salt bridges,' which are combined hydrogen bonding and electrostatic interactions between oppositely charged, hydrogen bonding-competent side-chains (e.g., lysine and glutamic acid).

Protein stability involves complex trade-offs between the configurational entropy of the protein backbone, the entropy of the solvent, and the favorable enthalpies of interaction between protein groups, such as backbone hydrogen-bonding within 2° structure, salt bridges, and London dispersion forces in the core (Figure 1). Enumeration of these terms typically identifies large opposing energetic contributions between enthalpy and entropy (e.g., ΔH and $|\Delta S|$ of folding are often $>400 \text{ kJ mol}^{-1}$ for small proteins) but with a small net balance (e.g., $20\text{--}30 \text{ kJ mol}^{-1}$) in favor of the native state structure. Thus, evolved proteins have a modest energetic preference for the folded conformation – a balance that can, in some cases, be disrupted by a single energetically unfavorable point mutation. For example, a single strong salt bridge can provide $10\text{--}15 \text{ kJ mol}^{-1}$ of favorable stability; thus, a mutation that eliminates one member of the salt bridge can cause protein unfolding (Anderson *et al.*, 1990).

Protein Folding Mechanisms and the Search for the Native State Conformation

The conformational space accessible to a protein is vast, and even a short protein of 100 amino acids can sample an astronomical number of conformations ($>10^{140}$). Thus, if a protein were to attain its correctly folded structure by sequentially sampling all of the possible conformations, it would require a time longer than the age of the universe to arrive at the correct native state – even if conformations are sampled at nanosecond or picosecond rates. Experimental studies of protein folding, in contrast, observe that the folding reaction occurs on the millisecond to second timescale, far faster than if the protein were sampling conformations at random (Levinthal, 1969). The above contradiction – first pointed out by Cyrus Levinthal and referred to as 'Levinthal's paradox' – suggests that for proteins to fold efficiently there must be a 'folding pathway' that biases the conformational search for the native state structure. Although the details of a

Figure 1 Basic structural and energetic principles of protein folding. Protein folding involves solvent entropy gain from the burial of hydrophobic groups (i.e., elimination of water clathrates), and enthalpy gain of favorable intra-chain charged, polar, and van der Waals interactions. The summation of these factors offset (slightly) the unfavorable protein conformational entropy penalty.

folding pathway are specific to both the amino acid sequence and native state structure of the protein, several general features have emerged leading to the belief that many proteins share a common ‘folding mechanism.’

Protein folding is nucleation-dependent, meaning that the folding reaction is initiated by a region of the polypeptide chain (the ‘folding nucleus’) that then templates the propagation of native structure to adjacent sites (Wetlaufer, 1973; Rackovsky, 1978). Early studies of protein folding noted that the common types of protein 2° structure (α -helix, β -hairpin, and β -strand) are examples of structures that, once nucleated, can be rapidly propagated to contiguous amino acids. Structurally this propensity for nucleation is due to correct positioning of the main chain amide and carbonyl hydrogen-bonding groups, which permits the addition of new partners that extend the 2° structure (Figure 2). Protein 2° structure is defined by either a repeating (α -helix, β -strand) or a specific sequential (e.g., reverse turn) backbone angle conformation, and the preference for a given type of 2° structure is heavily influenced by amino acid composition (Argos and Palau, 1982; Blaber *et al.*, 1993; Kim and Berg, 1993). Thus, ‘amino acid propensities’ for a given 2° structure can tune or control nucleation and propagation of 2° structure elements. The formation of protein 3° structure by nucleation is also feasible, and the two types of structure (2° and 3°) are free to form concurrently by establishing mutually reinforcing interactions.

A ‘molten globule’ is a term given to a polypeptide having defined 2° structure elements, a generally compact (i.e., collapsed) conformation, but no well-defined (i.e., tightly packed) hydrophobic core. It can exist in a protein whose stability has been perturbed by heat or chemical denaturants, and is also often observed as an undesirable feature of some *de novo* designed proteins.

Implicit in the terminology ‘folding pathway’ is the suggestion that protein folding proceeds via a well-ordered,

defined series of conformational transitions. Simulations of protein folding, however, challenge this view. Instead, the search for the native state likely proceeds with a high degree of variability early in the folding reaction, and becomes progressively more committed to an ordered pathway as the number of native-like interactions increases (referred to as zipping and assembly). Indeed, the progressive ordering of the folding pathway is analogous to the shape of the conformational ‘energy landscape’ upon which folding occurs, termed the ‘folding funnel’ (Leopold *et al.*, 1992; Figure 3). From the perspective of the folding funnel, native-like interactions are mutually reinforcing, and bias the subsequent conformational search toward productive pathways on the energy landscape. Because native interactions promote the formation of yet more native interactions, the need to sample huge numbers of conformations is avoided, thereby resolving Levinthal’s paradox (Levinthal, 1968; Dill and Chan, 1997). The folding funnel describes the efficient flux through a series of conformational states that become progressively less flexible (losing configurational entropy) but lower in energy.

Application of transition state theory to protein folding has permitted experimental characterization the ‘folding transition state,’ the key conformational ensemble that dictates the rate of the folding reaction (Dill, 1985). The folding transition state is the highest energy state along the pathway, and is envisioned as a saddle point along the energy surface. To date, a number of folding transition states have been characterized. Generally, the folding transition state is (1) structurally compact, (2) has limited regions of 2° and 3° structure with largely correct native interactions, and (3) shields a number of hydrophobic groups from solvent. The regions of the folding transition state that exhibit native-like structure are thought to be central to the folding process, and believed to be a key part of the folding nucleus. Loss of configurational chain entropy (discussed above) appears to be a central factor responsible for

Figure 2 Example of folding nucleation by protein 2° structure. Nucleation is the stochastic rate-limiting step in which local interactions set up an initial short region of organized 2° structure (either α -helical (upper panel) or β -strand (lower panel)). This short region of 2° structure correctly positions main chain amide and carbonyl groups to template rapid subsequent extension ('condensation').

Figure 3 The energy landscape and 'folding funnel' theory of protein folding (Leopold *et al.*, 1992). The folded structure is accessible via multiple pathways, each involving a cumulative increase in native contacts, favorable enthalpic interactions, and loss of conformational entropy. A key event is formation of the folding transition state which establishes a nucleus of native structure (with limited entropic cost) able to promote formation of additional native contacts.

the height of the barrier to protein folding because measures of topological complexity (e.g., the relative closeness of interacting pairs within the sequence of a folded protein) correlate

well with the observed rates of folding across a number of different protein architectures (Plaxco *et al.*, 1998).

Misfolding

The energy landscape of folding can be described by a folding funnel (Figure 3), as discussed above. The 'roughness of the walls' of the folding funnel is a key aspect of the conformational energy landscape. The local valleys indicate 'kinetic traps' that can slow folding, including conformations that may satisfy a subset of native-like attractive interactions, but are not compatible with the final folded structure (i.e., a misfolded conformation). Such a situation is termed 'folding frustration' and may require back-tracking, or partial unfolding, to a higher energy conformation before productive folding can proceed (Nymeyer *et al.*, 1998; Capraro *et al.*, 2008). Proteins are thus hypothesized to have evolved to optimize the energy of the folded conformation as well as to avoid 1° or 3° structure features that contribute to folding frustration, to yield a minimally frustrated, smooth energy landscape (Onuchic and Wolynes, 2004).

From the earliest days of protein structure determination it was realized that many protein architectures exhibit some form of structural symmetry – postulated to be the consequence of gene duplication and fusion events in their evolution from simpler structural motifs (McLachlan, 1972; Ohno, 1970; Tang *et al.*, 1978). For example, in the extreme case of the muscle protein Titin there are 132 copies of fibronectin type III domain and 112 copies of an immunoglobulin domain. Such repeating

Figure 4 Domain swapping resulting from gene duplication and fusion. (a) Shows a protein architecture (e.g., a four-stranded anti-parallel β -sheet) that has undergone duplication and fusion of its coding gene. (b) Shows how exact repetition of such a motif can alternatively fold by domain swapping. This alternative folding has different connectivities (and is distinct from the native structure in panel a), but has essentially equivalent native-like contacts and is therefore likely to be kinetically trapped in its folding.

motifs offer the potential for ‘domain swapping’ during folding (Bennett *et al.*, 1994), in which repeated domains exchange structural elements resulting in significant native-like (i.e., stabilizing) interactions but with an overall incorrect structure (Figure 4). In the case of exact repeating domains (as would occur immediately subsequent to any gene duplication and fusion event) such domain swapping could potentially generate ‘native’ architecture albeit with nonnative connectivities. The folding of proteins having repetitive motifs is an area of significant interest as such studies can inform aspects of protein evolution as well as *de novo* design. Favorable local interactions, control over connecting loop length and dynamics, and sequence asymmetry between repeating motifs can each shift the folding pathway of such proteins between native and domain-swapped/misfolded forms (Hakansson *et al.*, 2001; Dyer *et al.*, 2004; Wright *et al.*, 2005). The compatibility of ‘pure symmetry’ (i.e., exact repeating 1° structure within a symmetric 3° structure) to yield an efficiently folding polypeptide has been a matter of substantial debate; however, recent successes in this area have demonstrated both the utility of symmetry in the design of efficiently folding globular proteins and the plausibility of the gene duplication and fusion hypothesis of symmetric protein evolution (Lee and Blaber, 2011; Lee *et al.*, 2011; Broom *et al.*, 2012; Voet *et al.*, 2014).

Disordered Proteins

The properties of ‘intrinsically unstructured proteins’ rest at the interface of polymer physics and structural biology. Nearly

80% of eukaryotic proteins, to varying degrees, are characterized by regions believed to lack well-defined structure (on the basis of sequence analysis). However, because the tools of molecular biology and protein chemistry are particularly well suited for the study of compact, globular proteins, an understanding of the functional significance of proteins with a high degree of conformational flexibility has lagged behind that of structured proteins. In light of recent advances, proteins are now envisioned to exist on an order–disorder continuum, with completely structured proteins at one end of the spectrum and completely unstructured proteins at the other.

Among the most common disordered structural elements is the flexible linker – a stretch of amino acids that does not adopt a defined conformation, the main function of which is to tether two (structured) protein domains together. Tethered domains are not free to move independently through space; thus, the search of a ligand or substrate molecule that must interact with both domains (either simultaneously or sequentially) is dramatically reduced. ‘Loops’ are another structural element often present within the context of a well-folded protein scaffold. Like the flexible linker, though to a lesser extent, loops are characterized by a relatively high degree of conformational disorder. Structurally, loops permit a doubling back of the protein backbone that is not possible with the linear α -helix or β -strand 2° structure elements, thereby enabling globular protein architectures to be built up from what are fundamentally linear (i.e., fibrous) structural elements. In many proteins, extended loops are hotspots for conformational changes associated with function, and are frequently observed near enzyme active sites and ligand binding sites – controlling access and specificity of substrates.

‘Coupled folding and binding’ occurs when an unstructured polypeptide binds to a ligand (e.g., RNA, DNA, or another polypeptide) and the energy of binding induces protein folding. For functional proteins that lack well-defined structure, coupled folding and binding is a common theme. In the absence of ligand, these proteins have conformational properties more akin to the denatured state of a structured protein; with ligand bound, these proteins essentially adopt a ‘native state’ conformation. Structural characterization of unliganded proteins known to undergo coupled folding and binding have revealed ‘flickering’ (i.e., transient) native-like 2° structure (Tompa, 2005). Consistent with this view, studies that modulate the amount of 2° structure flickering within an intrinsically unstructured protein have demonstrated specific functional changes (Kennedy *et al.*, 2013).

There are two principle advantages of coupled folding and binding: First, it represents an approach to encode high-specificity, low-affinity interactions (Dunker *et al.*, 2002; Uversky, 2002). In the case of structured proteins, improvements in specificity would likely come at the cost of greater affinity. Biological networks, however, often rely on transient (labile) interactions but demand remarkable specificity. Thus, by coupling folding to binding, the entropic penalty associated with structuring the polypeptide resists binding (depressing the affinity for the ligand) while the precise alignment of chemical groups (a feature of structured proteins) can still be leveraged to achieve exquisite binding specificity. Second, proteins with a high degree of structural flexibility will, by definition, be characterized by a larger radius of gyration. It has

been suggested (Shoemaker *et al.*, 2000) that a larger radius of gyration results in a greater 'capture radius,' and increases the chances that the unstructured protein will encounter a cognate ligand. The features described above – highly specific, labile interactions and an expanded capture radius – may find use at the heart of a regulatory pathway or metabolic 'hub.'

A developing interest in the field of intrinsically unstructured proteins is understanding the role that these proteins play in phase separations known as nonmembrane-bound organelles. Cellular phase separations (which often contain, but do not require, RNA) are found in a myriad of biological processes, including neuronal granules, germ granules, and nucleoli (Weber and Brangwynne, 2012). Physically, phase-separated granules behave as liquid droplets with high viscosity, are spherical in shape, and can merge upon collision. Like traditional organelles, nonmembrane-bound granules provide a mechanism to co-localize high concentrations of key molecules both spatially and temporally for biological function. It has recently been noted that unstructured, low-complexity sequences are associated with granule formation, and cellular phase separations in general, though the exact mechanisms are still poorly understood. The ability of proteins to mediate phase separations within the cell speaks to the remarkable versatility of the polypeptide.

Related Diseases

Mutations that destabilize a protein may reduce the concentration of native (and therefore functional) protein, increase susceptibility to proteolytic degradation (a process that requires partial unfolding to bind to the protease active site), and increase aggregation (due to exposure of hydrophobic groups). With sufficient depletion of active protein, metabolic dysregulation leading to pathogenic conditions can emerge. A well-known example of such a mutation is the $\Delta F508$ variant of the cystic fibrosis transmembrane conductance regulator (CFTR), in which the CFTR protein has suffered a deletion of phenylalanine at position 508. This results in substantial destabilization of the protein (Sharma, 2001) such that it does not exit the ER/Golgi quality control system. As a result, the correctly folded form of CFTR never makes it to the cell membrane at significant concentrations, thereby blocking proper chloride transport. Small molecules, whose interaction with $\Delta F508$ CFTR can enhance folding or stability, may prove useful as a protein folding-based therapy to treat this debilitating disease (Pedemonte, 2005).

Another form of misfolding disease is amyloidosis, where misfolded proteins aggregate in an ordered manner to yield insoluble, fibrous plaques that deposit in extracellular tissue. The fibrils of such plaques are the macroscopic manifestation of continuously extended β -pleated sheets, a structural feature referred to as an 'amyloid.' In 1951 Linus Pauling, Robert Corey, and Herman Branson discovered the α -helix and β -sheet 2° structure 'building blocks' of proteins. These are low-energy conformations of the peptide backbone that satisfy local backbone H-bond requirements. Once established within a small region of a polypeptide, these 2° structures can nucleate further growth (condensation). Both types of 2° structure are fundamentally linear and are terminated by different

Figure 5 A β -barrel protein architecture. (a) Side view of a β -barrel (PDB accession 1QD6) where the β -strands comprising the β -sheet are oriented approximately vertically and the extension (i.e., growth) is consequently horizontal (i.e., normal to the β -strand axis); (b) Bottom view of the same structure illustrating how circularization of the sheet (i.e., barrel formation) effectively terminates the sheet extension. Adjacent sheets may be contained within the same polypeptide (as shown here) but are demarcated by reverse turn structure – thus, the β -sheet is effectively an inter- rather than intra-chain condensation growth. The structures are 'ribbon' diagrams colored by 2° structure (β -strand = yellow, α -helix = red, turn = gray).

types of 2° structure (typically reverse-turns) that are incompatible with further condensation. While the α -helix establishes local intra-chain H-bond interactions, the β -sheet can involve distal intra-chain or inter-chain H-bond interactions. In other words, an individual α -helix can extend only as far as the length of the polypeptide in which it is nucleated, whereas the β -sheet can continue to grow as long as new peptides condense onto the growing edges of the sheet. Thus, the β -sheet is much more capable of extensive, and potentially uncontrolled, growth – and it is believed that nearly any polypeptide sequence, under the right conditions, can form an extended β -sheet structure. Nature typically deals with this potential for out of control growth by forming a barrel (Figure 5) in which the β -sheet closes upon itself, neatly terminating its own growth. However, should β -sheets form peptides whose sequence disfavors curvature of the sheet, long insoluble fibrils can result (where the growing axis of the fibril is normal to the axis of the β -sheet). The gross assembly and consequent aggregation of such fibrils is associated with amyloid-based pathogenic diseases, most notably Alzheimer's disease.

One of the more fascinating amyloid-based diseases is transmissible spongiform encephalopathy (TSE), which includes bovine spongiform encephalopathy (BSE or mad cow disease) and Creutzfeldt–Jakob disease (CJD) in humans. The basis of the human disease is a misfolded form of a normal human protein found in the membrane of nerve cells called prion protein (PrP). In the native conformation, PrPc does not have a tendency to aggregate; PrPc, however, has an alternative, kinetically-trapped, low-energy conformation that favors aggregation into an amyloid structure. The amyloid form of PrP, (PrPsc) contains β -strand 2° structure that, once nucleated, can efficiently grow by the incorporation of additional PrPsc. The binding energy associated with incorporation is sufficient to drive the conformational conversion of normal PrPc into PrPsc. Thus, the infectious agent of CJD is a

misfolded protein, not nucleic acid, virus, or bacteria. This serves to highlight the fact that molecular complementarity (the basis of genetic information) can be found in molecules other than nucleic acids (indeed, yeast have been shown to use amyloid-based structures as a form of inheritance). Once the fundamental molecular complementarity of DNA bases was elucidated, interest in the potential of such properties in proteins essentially disappeared. Protein folding, misfolding, and amyloidosis, however, has prompted renewed interest in molecular complementarity within proteins.

Diseases of Protein Folding: Huntington's Disease and Amyotrophic Lateral Sclerosis

BJ Bailus and LM Ellerby, The Buck Institute for Research on Aging, Novato, CA, USA

© 2016 Elsevier Inc. All rights reserved.

Introduction

Huntington's disease (HD) and amyotrophic lateral sclerosis (ALS) are neurodegenerative diseases, which affect two different regions of the brain. Symptoms of HD include chorea, mental disturbances, mood changes, and dementia and are due to degeneration of cells in the striatum and cortex; while those with ALS exhibit difficulty moving limbs, muscle wasting, decline in cognitive function, and eventual respiratory arrest and are due to degeneration of upper and lower motor neurons of the cerebral cortex, brainstem, and spinal cord (Labbadia and Morimoto, 2013; Garbuzova-Davis *et al.*, 2011). Although there are no currently available treatments there is a large scientific community aggressively pursuing therapy options. Both HD and ALS are generally caused by a gain-of-function mutation in their respective genes that results in protein aggregation leading to disruption of protein homeostasis, altered ubiquitin-proteasome system (UPS) and cellular autophagy, eventually resulting in cellular death (Kiernan *et al.*, 2011; Ghavami *et al.*, 2014; Walker, 2007). The cellular dysfunction or death of the affected neuronal cells is the cause of the physiological symptoms. We will cover the genetic basis of each disease, the toxic mutant proteins, the

formation of the aggregates, the effect on protein homeostasis, and cellular autophagy. The theories on cellular transfer of aggregates and why neurons are specifically vulnerable to these toxic protein conformations will be explored. The conclusion will focus on the current trends in the field toward potential therapies and cures in the context of addressing protein homeostasis and autophagy.

Protein homeostasis, termed proteostasis, is defined as the correct maintenance of proteome in the cell, and the cellular activities associated with this, including folding, assembly, transport, repair, and degradation of proteins (Kikis *et al.*, 2010). It is imperative that damaged proteins are broken down and that the correct cellular balance of proteins is maintained for the cell to operate in an effective manner. A change in a protein conformation can alter the cellular function, concentration, and degradation of the mutated protein, impacting the cell's ability to maintain the correct protein homeostasis (see Figure 1). In a normal cell protein homeostasis is maintained through two main pathways, the ubiquitin dependent pathway and autophagy. The ubiquitin dependent pathway relies on a series of ubiquitin carrying proteins that transfer ubiquitin onto the target protein, usually tagging the protein for degradation by the proteasome. This pathway predominantly

Figure 1 A depiction of HD and ALS at a genetic and protein level. The mutant DNA is shown with either the expanded CAG region for HD, or a variety of possible mutations in the SOD1 gene for ALS. The DNA codes for a mutant version of the respective proteins HTT and SOD1, which have a tendency to form oligomers and then aggregates. The mutant proteins have unique proteolytic sites which result in toxic fragments. The cells preferentially secrete the mutant protein into the extracellular matrix, which are then taken up by neighboring cells, propagating the spread of the disease.

focuses on short-lived proteins. The other pathway, autophagy degrades longer lived proteins and cellular organelles utilizing the lysosome pathway (Ghavami *et al.*, 2014; Lin *et al.*, 2013; Cuervo *et al.*, 2005). Working synergistically with these pathways is a group of cleavage enzymes that help direct which pathway the protein are broken down through (Wellington *et al.*, 2000, 2002; Gafni and Ellerby, 2002).

Genetic Basis of HD and ALS

Huntington and ALS are diseases caused by autosomal dominant mutations that result in a toxic gain of function for their respective proteins. In autosomal dominant diseases only one allele needs to be inherited for the individual to be affected. The huntingtin gene has a series of CAG repeats in exon 1, normal repeat length is less than 36 repeats, and the disease state is more than 40 repeats (Walker, 2007; Mangiarini *et al.*, 1996). The CAG trinucleotide repeats code for the amino acid glutamine. This increased polyglutamine tract results in a toxic gain of function for the huntingtin protein (HTT), causing a conformational change leading to toxic fragment production, accumulation of oligomers, fibrils, and inclusions. The CAG repeat is genetically stable when the repeat length is less than 36, but as the length increases the genetic stability decreases, with a tendency toward increased repeat length, due to slippage during DNA replication (Petruska *et al.*, 1998). This slippage during DNA replication results in an increase of CAG repeat length for each successive generation of offspring. The length of the CAG repeat region correlates to the onset of the disease, the more repeats the earlier the onset of symptoms occurs (Andrew *et al.*, 1993; Krawczak *et al.*, 1991; Snell *et al.*, 1993). Since 1993, a genetic test has been available for individuals, who chose to utilize it (de Die-Smulders *et al.*, 2013; Myers, 2004). Along with HD, there are 16 different diseases caused by trinucleotide expansion triplet repeat expansions, collectively called trinucleotide repeat expansion disorders.

The function of the HTT (350 kDa) is not fully elucidated but the protein is composed of so called HEAT repeats and acts as a scaffold protein forming a large number of protein:protein interactions that give clues to its function (Tourette *et al.*, 2014). The HTT protein is found associated with organelles, is ubiquitously expressed and knockout of this gene is embryonic lethal, suggesting a fundamental cellular function for HTT. The HEAT repeat domains of HTT are predicted to act in molecular motion (Grinthal *et al.*, 2010) and are involved in vesicular trafficking, secretory vesicle fusion, autophagy, and cilia function (Pla *et al.*, 2014).

In ALS about 90% of the cases are sporadic, in which there is no previously known familial cause of the disease (Hardiman *et al.*, 2011). There are many causes potentially implicated in the disease including but not limited to head trauma, diet, and environment. The remaining 10% of the cases are genetic; over 40 different genes have been implicated in the disease. One of the most common mutations is a mutation in the SOD1 gene. Mutations in the SOD1 gene account for 2% of all ALS cases (Robberecht and Philips, 2013; Andersen and Al-Chalabi, 2011). Over 100 different mutations in the SOD1 gene have been characterized and implicated in ALS, the specific mutation will influence the manifestation and onset of symptoms

(Robberecht and Philips, 2013). Genetic testing is available for individuals, for the common familial associated mutations.

The SOD1 gene codes for a copper and zinc-containing enzyme called superoxide dismutase that protects against free radical damage detoxification of superoxide. The protein is ubiquitously expressed in the body. The mutations in SOD1 can result a conformational change in the protein that results in a gain of function, and protein aggregation (Robberecht and Philips, 2013). The deficiency in copper in the various genetic forms may be a factor that leads to the propensity of these disease proteins to form fibrillar SOD1 aggregates (Pratt *et al.*, 2014). Metal homeostasis may in general be altered in all forms of ALS (Lovejoy and Guillemin, 2014) and lead to altered protein homeostasis and aggregation. Both HD and ALS belong to a group of neurodegenerative diseases including Alzheimer's disease and Parkinson's disease called proteinopathies due to the propensity of the proteins to form aggregates.

Effects of Protein Products on Protein Homeostasis

In both HD and ALS the genetic mutations result in a gain of function, with the mutated proteins forming protein inclusion bodies. These protein aggregates accumulate in the cells, and have been implicated in affecting protein homeostasis, both as a detriment and as a compensatory mechanism for maintaining protein homeostasis. In HD the predominant species of protein found in the aggregates is HTT, in ALS the predominant species is SOD1. The inclusion bodies have ubiquitin and proteasome components. Although originally thought to be the causative agent of the disease, the aggregates formed from these mutated proteins are now considered to be the cells compensatory mechanism, as a way to maintain a modified protein homeostasis (Arrasate *et al.*, 2004). The formation of these aggregates into inclusion bodies has been shown to positively predict cellular survival, and decreases the amount of diffuse toxic huntingtin present in the rest of the neuronal cell (Arrasate *et al.*, 2004). In ALS the protein aggregates are composed of a mixture of SOD1, TDP-43, and other proteins (Kiernan *et al.*, 2011).

Cellular toxicity in both ALS and HD is considered to be a result of the smaller fragments that are created from the disease protein, and proteolytic events (Ellerby and Orr, 2006; Gafni and Ellerby, 2002; Gafni *et al.*, 2012; Hermel *et al.*, 2004). These fragments aggregate more readily in the cells, and their localization within the cell may determine their neurotoxicity on both HD and ALS (Arrasate *et al.*, 2004). The fragments are generated when the expanded or mutated transcript results in alternative proteolytic sites on the protein, resulting in the generation of smaller fragments. These smaller fragments appear to be less prone toward aggregation, the cells coping mechanism for larger fragments. The smaller fragments diffuse throughout the cell, evading the normal degradation pathways, disrupting cellular processes, and protein homeostasis (Warby *et al.*, 2008; Labbadia and Morimoto, 2013).

Clearance Pathways of Aggregates – Cellular UPS

One pathway that helps maintain proteostasis by protein degradation is the UPS. It is utilized by cells to reduce the

number of damaged proteins and represents a major mechanism of defense for post mitotic neurons. In UPS system operates by (1) targeting the protein for degradation by modifying its C-terminus with ubiquitin and (2) then subsequent substrate proteolysis in the proteasome. In HD and ALS there are numerous studies evaluating how the UPS is involved in the disease process. It is known that specific proteasomal inhibitors when added to cells, results in increased aggregation of the mutant HTT or SOD1 protein which are commonly referred to as inclusion bodies. In cells and post-mortem human disease tissue inclusion bodies include ubiquitin and proteasomal subunits (Katsuno *et al.*, 2014). It is hypothesized that the UPS system may be impaired at the targeting or proteolysis stage. Numerous experiments have tested whether the proteasomal activity is inhibited by inclusion bodies, but this does not appear to be the case. Studies have looked at whether inclusion bodies or conformationally altered proteins obstructed the channel of the 20S core subunit by preventing ubiquitinated substrates from entering the channel; this does not appear to be the case as the UPS is able to degrade polyQ expanded HTT and inclusions (Hoffner and Djan, 2014). The recruitment of the proteasomal is dynamic and cell biology studies show it is reversible with respect to inclusion bodies. Further studies suggest that it is not the inclusion bodies but the fibrillar or possibly oligomeric forms that interfere with the 26S proteasome. These mechanisms suggest a direct interaction of mutant HTT with the UPS system but additional studies are still needed for confirmation. Another possibility that the field is exploring is that the global proteostasis network could be perturbed by aggregated disease proteins and this would delay the maturation of cellular chaperone clients, increasing the overall number of ubiquitinated substrates, disrupting the UPS. A recent example is the demonstration that aggregation prone proteins such as mutant HTT and superoxide dismutase effect a fundamental cellular process-clathrin-mediated endocytosis through the heat shock protein 70. Clathrin-mediated endocytosis is required for AMPA receptor internalization and dysregulation could lead to neurodegeneration (Yu *et al.*, 2014).

Clearance Pathways of Aggregates – Autophagy Pathway

The second clearance pathway used to maintain proteostasis is known as autophagy, a process by which proteins and organelles (mitochondria, endoplasmic reticulum, and ribosomes) are sequestered into autophagosomal vesicles and delivered to the lysosome for degradation. The details of this pathway were worked out in yeast and there are four major steps involved. The genes Atg1p-Atg13p-Atg17p are involved in the first steps of autophagosome formation and this is regulated by nutrient signaling protein, mTOR. The Vsp34p-Vsp30p facilitates the assembly of the autophagosome via phosphoinositide signaling. The ubiquitin-like protein (UBL) conjugation cascade (Atg7p, Atg10p, Atg3p, Atg8p, and Atg12p) is used for autophagosome maturation and cargo recruitment. The last step involves the recycling system, Atg9p, Atg2p, Atg18p, and Atg21p to transfer and recycle components from the isolated membrane. In HD and ALS, a number of

these steps have been shown to be disrupted by the mutated protein and effects the degradation of aggregated proteins. In both HD and ALS there is increase number of autophagosomes and inhibition of mTOR. Mutant HTT has been shown to interfere with the ability of the autophagic vacuole in cargo recruitment (Koga *et al.*, 2011). In addition, a specialized form of autophagy called chaperone-mediated autophagy is increased in HD and appears to be a compensatory mechanism for clearing proteins; however, even with the upregulation of different forms of autophagy the mutant HTT is not cleared. Generally, it is understood that mild activation of autophagy can provide benefit in clearing the disease containing proteins but over activation leads to cellular dysfunction and ultimately cell death. Another pathway that appears to be important in clearing mutant HTT is through the scaffolding protein called ALFY which clears aggregated proteins via the lysosome and the levels of the ALFY protein are decreased in the HD striatum (Filimonenko *et al.*, 2007, 2010). The HTT has recently been proposed to function as an Atg11 and AT23 homolog and control aspects of cellular autophagy (Ochaba *et al.*, 2014). This data would suggest HTT has a critical protein for cellular pathways mediating clearance of proteins or organelles.

Cellular Transfer of Aggregates on Toxic Fragments

In HD it has been shown that both the aggregates and the fragments can be propagated both within the cell and by cell-to-cell transmission. Transmission is the ability of HTT fragments that are expressed in one cell type to spontaneously transfer to an adjacent cell. The transmission of mutant HTT has been demonstrated in mouse models of HD, in HD patients grafted with fetal tissue, in HD patients and in HD stem cells implanted into mouse brains. Further, when healthy human neurons were transplanted into HD mouse models, these neurons began to accumulate mutant HTT and display altered neuronal morphology. The spread of aggregates could have implications on how the disease progresses during aging and which regions of the brain are most vulnerable to this transmission mechanism. The exact cellular mechanics for this type of transfer have not yet been elucidated but appears to require the synaptic vesicle fusion machinery or cell surface proteins (Trevino *et al.*, 2012). For Tau, which exhibits similar aggregation and fragment tendencies when mutated in Alzheimer's disease, the transmission mechanism requires heparin sulfate proteoglycans (Holmes *et al.*, 2013). Research is currently progressing to better understand the precise mechanism used for HTT transmission.

One of the hallmarks of ALS is the progression of the disease, the outward spread of muscle atrophy from a central starting point (Hardiman *et al.*, 2011; Robberecht and Philips, 2013). It has been hypothesized that the propagation of symptoms is due to the propagation of the mutant SOD1 aggregates, both within an individual cell and from one cell to another. The intracellular concept involves a prion-like transmission in which a mutant form of the SOD1 will upon contact with a normal form of SOD1 influence the normal SOD1 into changing its confirmation and folding into a mutant-like confirmation (Munch and Bertolotti, 2011). This is a seeding effect in which one mutant protein will affect many

normal proteins, which in turn will change their conformation and affect other normal proteins (Fernandez-Borges *et al.*, 2013; Munch and Bertolotti, 2011; Munch *et al.*, 2011). This cascade of events eventually proves toxic for the cell, however this only effects a single cell. A broader question examines if a cell with mutant aggregates can transmit these mutant fragments to a neighboring cell and cause the same cascade event. Several studies have shown that in cell culture the secretion of mutant fragments and aggregates occurs, the neighboring cells internalize these mutant fragments through endocytosis, which then act as 'seeds' converting normal folded proteins into misfolded proteins (Munch and Bertolotti, 2011). The mechanism for SOD1 secretion is specific for mutant SOD1, which exhibits a gain of function by interacting with chromogranins A and B which lead to its secretion, and eventual transmission to neighboring cells (Urushitani *et al.*, 2006). This progression from cell to cell helps explain the progression of symptoms outward from a local starting point in ALS.

Cell Specificity and Susceptibility

In HD and ALS, the particular vulnerability of neurons to altered proteostasis could be the cause of the selective neurodegeneration observed in these diseases. Unlike neurons, which do not divide, dividing cells can dilute the misfolded protein through uneven division and the younger cells eventually no longer carry the misfolded or aggregated proteins. Neurons and potentially other specific cell types in the brain are particularly vulnerable to these toxic proteins because of their different ability to employ UPS, autophagy, or the chaperone network. For example, the activity of UPS is lower in the striatal cells when compared to cortical cells. This would lead to a reduced ubiquitination and clearance of the mutant HTT in the striatum, causing cellular dysfunction and death. The protein chaperone network, which assists in folding proteins, has distinct expression levels in different regions of the brain (Margulis and Finkbeiner, 2014). By analogy similar changes in the proteostasis network may give clues to the selective neurodegeneration found in ALS.

Symptoms and Treatments of the Disease

The physical manifestations of both HD and ALS on an organismal level are profound, both diseases exhibit massive neuronal death, enough to be distinguished on autopsies of the deceased patients (Figure 2; Osborn *et al.*, 2004). This massive neuronal death disrupts the brain affecting the patient's ability to perform movements and in many cases cognitive functions. In HD the region with the highest incidence of neuronal death is the striatum, particularly the medium spiny neurons. Medium spiny neurons are GABAergic neurons, which have an inhibitory effect on the neurons they are in contact with, these neurons are essential in the coordinating movement (Tepper *et al.*, 2008; Walker, 2007). The progressive neurodegeneration leads to in chorea, a movement disorder associated with HD, in which the patient exhibits spastic, involuntary movements. Tetrabenazine, is currently one of USDA approved drug for treating chorea, it works by

Figure 2 Huntington's disease protein, aggregation and pathology. The upper panel is a comparison of HTT protein with a normal CAG repeat size compared to a mutant HTT with an expanded CAG repeat size and the aggregation. Macroscopic image in which a slice of Huntington's brain (left) is put next to a slice from a normal control (right). Note that the striatum (the caudate nucleus, putamen, and nucleus accumbens), on the left, is severely atrophied in the Huntington's brain. Note also that the cerebral cortex is atrophied in the Huntington's brain. Photo courtesy of the Harvard Brain Tissue Resource Center.

inhibiting dopamine receptors (Zheng *et al.*, 2006; Huntington Study, 2006; Poon *et al.*, 2010). Beyond the physical symptoms, HD patients experience cognitive decline, depressive episodes, mood swings, and obsessive behavior (Montoya *et al.*, 2006; van Duijn *et al.*, 2007). The behavioral and cognitive changes increase as the disease progresses, treatment involves the standard psychiatric medications. The mutant HTT is expressed throughout the body tissues, leading to muscle atrophy, cardiac failure, impaired glucose tolerance, osteoporosis, and weight loss (van der Burg *et al.*, 2009). These symptoms can be treated with a combination of physical therapy, diet changes, and medications. There are no HD specific drugs or treatments and there is no cure, the eventual outcome of the disease is death.

ALS progresses at a much more rapid rate than HD, usually resulting in death within 3–5 years of the first symptoms (Robberecht and Philips, 2013). In ALS the patient first notices difficulties moving an extremity, this progresses toward muscle atrophy, whole body movement difficulty, and eventually respiratory failure (Kiernan *et al.*, 2011). These symptoms are due to axonal retraction, death of the neuron, and denervation of the muscles, resulting in paralysis (de Carvalho *et al.*, 2010). In a subpopulation of patients the prefrontal and temporal cortex are affected to a degree which results in dementia (Phukan *et al.*, 2007). A subsection of the patient population

Figure 3 Use of induced pluripotent stem cells for therapeutics. Summarized are the steps for the use of induced pluripotent stem cells for autologous stem cell therapy in genetic diseases. (1) First skin cells are collected from patient; (2) then the cells are reprogrammed into pluripotent stem cells; (3) the stem cells are genetically corrected to remove the disease mutation; (4) the induced pluripotent stem cell is converted into the relevant cell type needed in the disease; and (5) finally the cells are transplanted into the patient.

does not experience any cognitive decline and is fully aware of their slow paralysis. The progression and severity of symptoms is dependent on both the type of genetic mutation and the age at onset of symptoms, creating a very heterogeneous population of patients in symptoms and survival time (Kiernan *et al.*, 2011; Hardiman *et al.*, 2011). No cure exists and medications are mostly focused on reducing symptom severity, Riluzole has shown some promise in increasing survival time, if given in the early stages of the disease (Carlesi *et al.*, 2011).

Potential Treatments and Therapies

There are three main treatment strategies being pursued for HD and ALS, drugs, stem cell therapies and genetic manipulation. The most conventional is drug screening for small molecules that will either delay the progression of the disease or ameliorate the symptoms of the disease. Several experimental drugs have been tried including Rapamycin in HD and Minocycline in ALS and HD (Ravikumar *et al.*, 2006; Berger *et al.*, 2006; Van Den Bosch *et al.*, 2002; Plane *et al.*, 2010). These drugs have side effects that have made them undesirable for long-term treatment. Rapamycin inhibits the TORC1 complex and has become a drug of interest for HD with the elucidation that the TORC1 complex of the mTOR pathway has been shown to interact with mutant HTT (Pryor *et al.*, 2014). Unfortunately Rapamycin has side effects including diabetic-like symptoms and lung toxicity (Lamming *et al.*, 2012; Pham *et al.*, 2004; Chhajed *et al.*, 2006). Minocycline, a candidate drug for both HD and ALS was found to be ineffective in HD and exacerbated the progress of ALS, perhaps through increased immunosuppression (Gordon *et al.*, 2007; Plane *et al.*, 2010; Huntington Study Group, 2010). Drug

screening for small molecules continues and there are several ongoing Phase II clinical trials for ALS and HD (Shefner *et al.*, 2013). As more information is discovered about HD and ALS more potential targets are revealed. The potential for stem cell therapies is being explored in both HD and ALS, in HD it has been shown in mice that injections of stem cells in the brain can have a beneficial effect on symptoms, for ALS there are ongoing human trials to evaluate the efficacy of this treatment in muscles (An *et al.*, 2012; Sadan *et al.*, 2009; Cohen, 2013). The main challenge for these experiments is the successful genetic modification of the stem cells and the delivery of them to the appropriate local within the patient (Figure 3). The third strategy involving genetic modification has advanced dramatically in the last 5 years as newer and more reliable tools have emerged in the field. Several group of DNA modification enzymes (Zinc Fingers, TALEs, and CRISPR) have the ability to replace the mutant gene with a modified nonmutant copy of the gene, or to regulate transcription levels (An *et al.*, 2012, 2014; Bailus and Segal, 2014; Segal and Meckler, 2013). The major challenge of this technology is efficiency and deliverability. Gene modifying tools are currently being utilized to modify stem cells, which are then injected into the patient in an effort to replace the damaged and dead cells with new nonmutant protein coding cells (An *et al.*, 2014; Hou *et al.*, 2013; Horii *et al.*, 2013; Yin *et al.*, 2014; Ye *et al.*, 2014). As more is understood about HD and ALS better therapies can be designed and delivered to patients in an effort toward increasing life span and survival rate in patients.

Site-Directed Mutagenesis

KW Walker, Amgen Inc., Thousand Oaks, CA, USA

Background

Site-directed mutagenesis (SDM), sometimes referred to as site-specific or directed mutagenesis, is a method of altering the nucleotide sequence of a gene at a specified location, which stands in contrast to general mutagenesis that employs mutagenic compounds or high-energy radiation to randomly alter DNA. SDM is a highly versatile technology that can be used to probe gene function of an isolated gene product in the context of a complex biological system, and it can be used to engineer proteins and even entire organisms for new functions or capabilities. The magnitude of the impact and widespread use of this technology in the biological sciences can be partially appreciated by conducting a PubMed search of the term 'directed mutagenesis,' which identifies 68 832 citations (as of April 2014).

The revolutionary approach that allowed for flexible SDM employing DNA polymerase and the primer extension method was pioneered by Clyde Hutchinson and Michael Smith in 1978, for which Michael Smith shared the 1993 Nobel Prize in Chemistry with Kary Mullis who developed another key technology for SDM, polymerase chain reaction (PCR). While the techniques evolved substantially over time, the fundamental aspect of employing mutation containing primers and DNA polymerases is still the cornerstone of modern techniques.

Methods

The basic technique for SDM employs a short synthetic DNA primer containing the desired mutation (base changes, deletions, or insertions), which is then hybridized to the template DNA that contains the parental gene of interest (GOI). The hybridized primer is then extended using DNA polymerase to duplicate the remainder of the GOI, which is then inserted into a host vector to enable propagation and expression of the mutated gene. The final step requires sequencing of the GOI to select those clones that contain the desired mutation. Modern variations of this process include the QuikChange method (Figure 1), which employs a pair of complementary primers containing the desired mutation, which are employed to synthesize the entire plasmid using a high-fidelity non-strand displacing polymerase such as *pfu* (Zheng *et al.*, 2004). The template DNA is then eliminated by enzymatic digestion with a restriction enzyme specific for the methylated template DNA, which enables elimination of the parental copy of the GOI. For multisite mutagenesis, alternative strategies such as Golden GATEway (Kirchmaier *et al.*, 2013), which is a cassette mutagenesis strategy that does not require retention of the restriction site; multiple patch cloning (MUPAC) (Taniguchi *et al.*, 2013), which is designed for introducing up to nine point mutants in a single GIO; as well as sequence and ligation independent cloning (SLIC) (Li and

Elledge, 2007), which is a cassette mutagenesis strategy that also allows for multiple mutations in a single reaction, are all excellent options. Additionally, with the substantial reduction in the cost of synthetic DNA primers, it is also practical in many circumstances to synthetically produce a cassette that is bordered by two unique restriction sites, or even the entire GOI, with the desired mutations.

Applications

SDM can be employed to substitute single or multiple amino acids in a protein, remove or insert amino acids, and alter the noncoding regions of a gene such as regulatory elements (Figure 2). Ultimately these directed changes can be used to probe biological systems for structure–function relationships, such as determining critical residues for enzyme catalysis or

Figure 1 QuikChange method of SDM. The first step employs a template plasmid, methylated (blue), containing the GOI, the accurate *pfu* DNA polymerase, and complimentary primers (red arrows) containing the desired mutation (purple dot) which replicate the DNA with the mutation producing non-methylated (red) DNA. The methylated parental plasmid is then digested with *Dpn I*, while the non-methylated mutant containing plasmid is resistant to degradation. The nicked mutation containing plasmid is then transformed into a host cell where the nick is repaired, it is replicated and methylated.

Figure 2 Applications of SDM. SDM is used to probe structure–function relationships including catalytic residues, binding-site residues, and regulatory elements. In addition, SDM is used to engineer proteins to enable enhanced function, increased stability, and site-selective conjugation.

substrate/cofactor binding, as well as identifying residues involved in regulating protein function. In addition, SDM can be employed to engineer new properties into proteins such as altered substrate specificity, thermal stability, and site-directed conjugation, all of which have applications in research and biotechnology. A powerful variant of SDM is alanine scanning mutagenesis, in which every residue in the entire protein, or region of interest, is individually changed to alanine and the functional properties of the variants are assessed (Cunningham and Wells, 1989). This allows for a systematic determination of the structure–function relationship of each amino acid in a protein without structural information or prior knowledge of the residue’s role. A notable advantage of alanine scanning mutagenesis is that it can identify allosteric effects and often leads to unexpected findings which broaden our knowledge of protein architecture.

Protein Structure–Function

Catalytic residues

Prior to the advent of SDM, identification of the catalytic residues in an enzyme was a painstaking process often involving chemical modification of the protein followed by peptide mapping and sequencing. However, SDM allows for the direct probing of the functional significance of residues suspected of being involved in enzyme-catalyzed reactions, and often enables subtle mechanistic determinations. For example, shortly after the development of SDM, it was employed to determine that Cys-35 in tyrosyl-tRNA synthetase, Glu-165 of triphosphate isomerase, and Asn-155 of subtilisin are all involved in stabilizing the transition state of their reaction intermediates. This was accomplished by changing these residues to other amino acids and observing the effect on enzyme function (Wilkinson *et al.*, 1983; Straus *et al.*, 1985; Bryan *et al.*, 1986). SDM can also be used to probe the catalytic roles of proximal and identical residues that cannot be segregated by chemical probes. For example, it was determined that chemical modification of Lys-83 or Lys-84 in aspartate transcarbamoylase inactivates the enzyme; however, it was not possible to determine if either or both residues were required. By mutating each residue individually it was demonstrated

that only Lys-84 is essential for catalysis, since substitution of Lys-83 with Gln does not significantly impact activity while this substitution abolishes activity at position 84 (Robey *et al.*, 1986). SDM was also used to dissect the novel mechanistic role of two nearby active site cysteines in protein disulfide isomerase, demonstrating that one is responsible for attacking the substrate disulfide bond creating a covalent complex with the substrate, while the other acts as a timer releasing the covalently bound enzyme, should the enzyme become kinetically trapped with the substrate (Walker and Gilbert, 1997).

SDM is also very useful for confirming homology model predictions by mutating residues predicted to have functional roles to determine if the expected outcome is achieved. This technique involves predicting the tertiary structure of a protein by sequence alignments to related proteins with known structures and then computationally generating a three-dimensional model of the target protein. Since the resulting model is only a prediction, SDM can be used to verify the accuracy of the model as demonstrated by Vasu *et al.* (2012) for *cis*-epoxysuccinate hydrolase where SDM was employed to validate the residues hypothesized to be part of a catalytic triad.

Binding sites

SDM is also a very powerful tool for mapping and verifying the residues predicted to be critical for substrate recognition, cofactor binding, and protein–protein interactions. For example, computational alanine scanning mutagenesis was used to identify potential substrate interactions sites in maltotriose trehalohydrolase. The *in silico* scanning mutagenesis predictions provided insight into residues potentially involved in trehalose binding, which were subsequently confirmed by actual mutagenesis studies (Fu *et al.*, 2013). SDM is also frequently used to probe the functional role of metal binding sites. For example, Kiraly *et al.* (2009) used SDM to alter residues of five Ca^{2+} binding sites in human transglutaminase 2, which allowed them to determine that while all five Ca^{2+} ions influence transglutaminase activity, only two of the sites are involved in GTPase activity and only one is responsible for determining the antigenicity associated with celiac disease.

Even when structural information is available to assist in identifying substrate or cofactor interacting residues, SDM is

critical for determining if the crystal structure identified interactions are significant in the solution phase and are not artifacts of crystallization. Ouyang *et al.* (2013) employed a combination of alanine scanning mutagenesis and salt-bridge residue substitutions to demonstrate that many of the side chains of HIV-1 nucleocapsid protein predicted by the crystal structure to interact with Zn^{2+} ions do not significantly contribute to the stability of the complex. In another example of SDM being used to clarify misleading crystal structure interactions, Koch *et al.* (2012) demonstrated that solution binding to a glutaminyl cyclase inhibitor in solution was different than that observed in the co-crystal structure.

In some cases, a combination of chemical modification and SDM can be used in concert to probe protein-protein interactions. For example, Bradshaw *et al.* (1994) employed this combination of techniques to demonstrate that aromatic residues are critical for stabilization of nerve growth factor dimer, while surface lysine residues from both subunits in the nerve growth factor dimer are responsible for receptor interactions.

Regulatory elements

SDM can be used as a powerful probe to identify and confirm the role of specific amino acids in the regulation of protein activity, and it is most frequently employed to probe the role of known and putative phosphorylation sites. Mutations that eliminate phosphorylation potential (i.e., alanine substitutions for serine and threonine and phenylalanine substitutions for tyrosine), when coupled with mass spectrometry, can be used to determine if the predicted site is actually phosphorylated, and it can be used to determine if phosphorylation of that site impacts protein function. For example, the role of tyrosine phosphorylation on fibroblast growth factor receptor 1 signaling was investigated by mutating the endodomain tyrosines to phenylalanine and observing the impact on cellular differentiation, resulting in the identification of two tyrosines critical for bioactivity (Foehr *et al.*, 2001). In another example, the functional role of multiple phosphorylation sites on the viral NS1 protein was dissected by individually mutating the phosphorylation sites and determining the impact on NS1 activity. This resulted in identification of two new *in vivo* phosphorylation sites and demonstrated that certain phosphorylation sites were responsible for switching the virus from productive to cytotoxic functions (Corbau *et al.*, 2000).

It is also possible to mimic phosphorylation of serine and threonine residues by converting them to aspartic or glutamic acid, which has a charge and structure similar to phosphoserine and phosphothreonine. For example, Woods and colleagues individually mutated three potentially phosphorylated serines and threonines to acidic residues in order to mimic phosphorylation and determine their role in AMP-activated protein kinase (AMPK), a protein responsible for energy metabolism regulation. Using this method, they were able to determine that only one of the three residues was involved in AMPK activation, thus extending the mechanistic understanding of an important target for developing therapeutics for treating metabolic disorders (Woods *et al.*, 2003). An alternative indirect SDM-based method used to identify phosphorylation sites employs incorporation of basic residues to

create nonnatural tryptic digest sites enabling cleavage of complex phosphoproteins into more manageable segments for mass spectroscopic analysis. This method was employed with the checkpoint protein kinase resulting in identification of 17 novel phosphorylation sites in this complex glycoprotein (King *et al.*, 2007).

Protein Engineering

Altered function

SDM can be employed to change the substrate specificity of an enzyme, which is a powerful tool for probing enzyme mechanism as well as enabling proteins to catalyze new chemistries of use for scientific and industrial applications. For example, Wiersma-Koch *et al.* (2013) were able to alter the substrate preference of the nucleotide pyrophosphatase/phosphodiesterase from a 10^6 -fold preference for diesters over monoesters to equal activity on both substrates with a 10^{11} -fold rate enhancement for the monoester. This was accomplished by using structural information to predict the substrate binding pocket followed by mutating four of those residues to generate the greatly enhanced enzyme, which is of use for biomedical and industrial applications. In another example of altering enzyme substrate specificity, mutation of a single residue in lysyl-tRNA synthetase, which converts ATP into diadenosine tri- and tetraphosphates, altered Zn^{2+} binding, resulting in greatly reduced diadenosine formation activity, ultimately shifting the protein to a substantially different function as a glycerol kinase (Chen *et al.*, 2013).

Homology modeling is a powerful method that can be employed to identify substrate binding residues in two related enzymes that have differing substrate specificities, allowing one to predict how the binding sites may be changed to alter substrate specificity for protein engineering applications. This was demonstrated by mutating two of the binding-site pocket residues of a purine-specific nucleoside hydrolase, converting it into a protein that is capable of hydrolyzing both purines and pyrimidines (Porcelli *et al.*, 2012). Homology modeling was also employed to predict the residues involved in the substrate specificity profile of a eukaryotic methionine aminopeptidase using the prokaryotic isozyme crystal structure. This information was used to create variants of the eukaryotic enzyme that have a broadly enhanced substrate profile, which can be used to produce native amino termini in recombinantly produced proteins for research and pharmaceutical applications (Walker and Bradshaw, 1999). In a unique approach to alter substrate specificity, Hui *et al.* (2013) employed both SDM and chemical conjugation to alter the substrate specificity of a lipase. They mutated an alanine to a reactive cysteine, and then chemically coupled that cysteine to thio-nitrobenzoic acid. This provided stronger steric exclusion and structural rigidity to the protein, which resulted in substantially enhanced diastereopreference with potential application in synthetic chemical production.

Stability

SDM has been widely employed to enhance the stability of proteins to thermal, pH, and oxidative stress. Increased protein stability is particularly useful for research, pharmaceutical, and

industrial chemistry applications, since reactions are often much more efficient at elevated temperatures, more extreme pH, and often occur under conditions that would put many proteins at risk for oxidative inactivation.

Thermal

Increases in the thermal stability of enzymes is often critical to enable the proteins to remain active at the high reaction temperatures often required for specific applications in both research and industry. For example, in order to develop a DNA polymerase that is active at the high temperatures required during PCR, while maintaining an exceptionally high fidelity, two point mutations were incorporated into *Thermococcus cel-ericrescens* DNA polymerase. These changes produced an enzyme with enhanced thermo stability, while maintaining its substantially lower error rate compared to *Taq* DNA polymerase, thus enabling long and accurate PCR of large gene segments (Kim *et al.*, 2011). In another example, to improve the production of D-amino acids for use in pharmaceuticals and the food industry, five point mutations were incorporated into a mesophilic D-amino acid dehydrogenase, enabling it to maintain complete activity at 65 °C and greatly enhancing its industrial utility (Akita *et al.*, 2012).

The food industry is a major user of enzymes, and improvements in thermal stability are often required to make the enzymes practical for this application. For example, pullanase can be used for starch debranching during the production of high glucose syrup; however, the wild type enzyme has relatively low stability and catalytic efficiency preventing its widespread application. To accomplish this, Duan *et al.* (2013) incorporated two point mutations in pullanase improving the half-life at 60 °C by 4.3-fold and increasing its catalytic efficiency by 100%, enabling industrial use of the enzyme. Another starch processing enzyme, α -amylase, achieved a melting temperature increase of 26 °C by employing two point mutations combined with a two amino acid deletion to produce an enzyme that could operate effectively at 70 °C (Kachan and Evtushenkov, 2013).

pH

Often the pH optimum of an enzyme does not match the pH of the environment for which it is needed, providing an opportunity for SDM to produce a better match between the protein and its operating environment. For example, bio bleaching in the pulp and paper industry requires both high temperatures and alkaline pH; however, known xylanases, which can catalyze bleaching reactions, do not function under those conditions. To address this, Zheng *et al.* (2014) combined three point mutations and one nonnative disulfide bond to increase the pH optimum of xylanase from 7.0 to 9.0 and increase the optimum temperature from 60 to 70 °C. In some circumstances, a more acidic pH optimum is required, such as for β -mannanase, which could be included in animal feed to increase the availability of manno-oligosaccharides, important as growth factors for beneficial intestinal microorganisms. Since the intestinal pH is low (5.5–6.0), a β -mannanase with a single point mutation was developed that dropped the pH optimum of the enzyme from 6.5 to 5.5 enabling its practical use as a feed additive (Xu *et al.*, 2013).

Oxidative

Many applications for enzymes expose them to an oxidative environment which can often result in inactivation of the protein. Although methionine, cysteine, and tryptophan are all susceptible to oxidation, methionine is frequently the most problematic residue, due to its higher oxidative vulnerability compared to tryptophan and its much wider prevalence, compared to reduced cysteine, in enzymes important for research and industrial applications. Generally only a sub-population of the oxidation vulnerable residues need to be changed to maintain function, since many are buried in the protein, and thus, not exposed to the oxidant, or they are not critical for activity. For example, *N*-acetyl-D-amino acid amidohydrolase is useful for the production of D-amino acids used in food and pharmaceutical products; however, this protein is susceptible to inactivation through methionine oxidation. Peng *et al.* (2012) were able to engineer this enzyme to increase its half-life by 6-fold and its catalytic efficiency 2.4-fold by mutating a single methionine to leucine. Enzymes are also frequently used in laundry detergent to enhance cleaning; however, oxidants are often present in the detergent, which can inactivate many enzymes. To address this, a single methionine in α -amylase from *Thermotoga maritima* was mutated to alanine enabling the enzyme to maintain 50% of its activity in the presence of 100 mM hydrogen peroxide, conditions under which the wild type enzyme is completely inactive (Ozturk *et al.*, 2013). Enzymes are often useful for bioremediation applications, which frequently require exposure to harsh environments. For example, the recalcitrant anthraquinone dyes often present in wastewaters are good targets for bioremediation using the unique *Anabaena* peroxidase; however, this enzyme is susceptible to oxidative inactivation in the presence of the required quantity of hydrogen peroxide. Mutation of a single methionine residue to phenylalanine enabled this enzyme to operate in the presence of 5 mM hydrogen peroxide enabling its use for wastewater management (Ogola *et al.*, 2010).

Site-selective conjugation

SDM can be employed to create specific positions on a protein for selective modification by creating a unique chemically reactive handle for immobilization or conjugation to a chemical moiety, or it can be used for directing cell mediated post-translational modifications such as glycosylation. For example, aequorin is a photoprotein that emits light upon calcium binding and is useful as a calcium sensor in some applications that require immobilization of the protein. In order to allow site-selective immobilization of aequorin, the native cysteines were selectively mutated to non-thiol containing residues, and then a cysteine was incorporated at a new site on the protein, which provides a unique thiol nucleophile that can be coupled to a wide variety of solid substrates (Lewis *et al.*, 2000). This allows for site-selective coupling of aequorin to the solid surface in a uniform manner that prevents inactivation often associated with random coupling.

Use of endogenous proteins as biotherapeutics often requires addition of large polymers such as polyethylene glycol (PEG) to improve pharmacokinetic performance and reduce injection frequency. While random PEG attachment has been employed in the past, it is highly preferable to produce a

uniform product in order to maximize bioactivity and reduce lot to lot variability. In the case of fibroblast growth factor 21, reactive cysteines residues were engineered on to the surface of this metabolic regulatory protein to allow for site-specific PEG conjugation. This enabled production of a uniform protein with substantially improved pharmacokinetic properties appropriate for potential application as a therapeutic for type II diabetes (Xu *et al.*, 2013).

An alternative to *in vitro* conjugation of synthetic molecules at engineered sites for serum half-life enhancement of therapeutic proteins involves the addition of sialated glycans during expression in the cell producing the recombinant protein. This approach has the advantage over synthetic conjugation in that it does not require an additional conjugation and subsequent purification step during the manufacturing process. Erythropoietin was modified in this manner by incorporating five mutations, creating two new consensus N-glycosylation sites, resulting in a protein, darbepoetin alfa, with a 3-fold improvement in the serum half-life, thus decreasing the number of injections required to achieve the therapeutic effect (Egrie and Browne, 2001).

Summary

SDM is a tremendously powerful technique that allows us to probe the function of highly complex protein molecules in a very precise manner, and it allows us to engineer proteins to enhance their functions. Even though SDM was developed over 35 years ago, application of this technology continues to accelerate due to the increasing need to investigate complex biological systems and the expanded demand for engineered proteins for research, food processing, organism engineering, bioremediation, high-value chemical production, and pharmaceutical applications. Increases in the efficiency of SDM, coupled with lowering costs, is enabling widespread application of this technology to enhance our understanding of biology and create novel proteins to address a wide variety of technological needs.

Glossary

Biomacromolecule A polymer associated with biological systems. Examples include nucleic acids, proteins, and polysaccharides.

Bioorthogonal modification The process of covalently modifying a biomacromolecule in a complex biological environment such as cell lysate or intact cell in a selective manner without a negative effect on normal cell function.

Click Chemistry A general term describing a simple chemical reaction joining two molecules; the term is used most frequently to describe alkyne-azide cycloaddition.

Metabolic labeling An experimental approach where the metabolic pathways inside a cell are used to label a protein

or other macromolecule with a label or reactive groups.

Examples of metabolic labeling include stable isotope labeling of proteins or the insertion of a reactive group into a protein during the synthetic process. Much earlier examples would include the use of radioisotopes to trace metabolic pathways.

Structural biology The study of macromolecular structure and supramolecular structure. Objects of interest range from proteins to organelles such as mitochondria and ribosomes. Techniques include computational biology, crystallography, nuclear magnetic resonance, and electron microscopy.

Introduction

The term chemical biology was first used in a lecture by Professor J.B. Leathes before the Royal College of Physicians in 1930 (Leathes, 1930). Professor Leathes made the case that the role of chemistry in biology was seen by William Harvey and others in work stemming discovery of the circulation of the blood. Some years later, Maurice Florkin used the term chemical biology in the title of a rather nice book in 1960 (Florkin, 1960). An historical perspective of chemical biology can be obtained from a treatise on the inhibition of enzymes by chemicals (Webb, 1963–66). One could make an argument that Webb's book (Webb, 1963–66) which was entitled *Enzymes and Metabolic Inhibitors* should have contained the term chemical biology in the title. Iodoacetate was used to define the early processes of glycolysis by inhibition of zymase, the enzyme responsible for the breakdown of glucose (Webb, 1966). Iodoacetate is still used as a metabolic poison to cause energy depletion (Jackson *et al.*, 2014).

Chemical biology has evolved into a term referring to the study of biochemical processes occurring inside of a live cell. It is important to accept that there is considerable overlap between chemical biology and biological chemistry such that *BMC Chemical Biology* is incorporated as section within *BMC Biochemistry*. Another example is provided by the transition of *Journal of Peptide Research* to *Chemical Biology and Drug Design*. Chemical biology is a broad area of investigation as demonstrated by the diversity of titles in the various journals in this area. This article has focused on topics within chemical biology that distinguish chemical biology as a separate discipline from other biological sciences.

Imaging

In a sense, chemical biology is not so much a specific discipline such as biochemistry, chemistry, or physics but more of a framework to use current tools to ask interesting questions. If you define chemical biology as an approach to 'look' at the

chemistry of the living cell, then methods by which one could see inside the cell at the molecular level would be most useful. This would be a form of molecular imaging directed at the cellular level. Molecular imaging, though, is a term that has seen most use in application for diagnostic radiology for whole animal studies (Rudin, 2009). Molecular imaging in chemical biology utilizes major advances in optical microscopy (Eggrling and Heilemann, 2014) as well as developments in spectroscopy including near-infrared fluorescence (Hilderbrand and Weisleder, 2010) and Raman microscopy. The spectral characteristics of the alkyne functional group show strong Raman scattering in a region where cellular constituent have null scattering (Yamakoshi *et al.*, 2012). Alkyne-labeled coenzyme Q analogues were measured inside living cells using Raman spectroscopy. Raman spectroscopy has also been used to image the distribution of tyrosine kinase inhibitors such as imatinib and nilotinib inside a living cell (Fu *et al.*, 2014).

Investigators (Korbas *et al.*, 2011) used synchrotron-based X-ray fluorescence imaging to show different cell and tissue distribution of inorganic and organic mercury in zebrafish embryos. The imaging can be considered an extension of earlier work on histochemistry, immunohistochemistry, and enzyme histochemistry but with more sophisticated optics and reagents. An example of such progress can be seen from the study on the imaging of peroxynitrite in cells with a fluorescent probe (Peng *et al.*, 2014). Reaction of peroxynitrite with HKGreen-4 which is not fluorescent results in the loss of aryl substituent and the formation of *N*-methylrhodol which is fluorescent (Figure 1) permitting the identification of peroxynitrite in cells. The design of increasingly complex substrates has yielded substrates with useful specificity such as shown for caspase-3 (Figure 1; Vickers *et al.*, 2014) permitting intracellular localization.

Metabolic Labeling

Metabolic labeling is a technique which involves the development of reactive substrates which can act as reporter groups

Figure 1 Some technical approaches in chemical biology. At the top is shown the visualization of peroxynitrite in the cell by reaction with *N*-Green-4. Below that is a fluorescence resonance energy transfer (FRET) substrate used for the intracellular visualization of Caspase-3. At the bottom is shown examples of metabolic labeling with an azide-hexamine used for labeling glycans and thymidine analogous for nucleic acids.

(Zurkin *et al.*, 1977) inside the living cell. The key to this approach is the development of a substrate analogue which contains a functional group which is unreactive to cellular constituents but which can be tagged with a reporter groups such as a fluorophore. An alkyne group is an example of such a functional group. *N*-acetyl hexosamines are precursor of glycoproteins and the acetyl function may also enter the pathway for carbohydrate metabolism. Although acetyl-coenzyme A derived from glycolysis serves as the acetyl group for protein acetylation, there is some evidence to suggest the acetyl function from *N*-acetyl hexosamines can also be a source of acetyl groups for protein acetylation. The *N*-acetylation of proteins is a posttranslational mechanism as important as a regulatory process in cell biology. The use of 1-deoxy-*N*-pentynyl glucosamine (Figure 1) suggested that there was a transfer of the pentynyl group to proteins (Zaro *et al.*, 2014). The pentynyl group could be labeled by an azide probe via click chemistry permitting the attachment of a fluorophore. A peracetylated glucosamine derivative was used to facilitate transport into the cell; the *O*-acetyl groups were removed by cytoplasmic esterases. Use of *N*-pentynyl glucosamine resulted in incorporation into *O*-glycans as well as the putative transfer of the pentynyl group to lysine residues on proteins. The use of the 1-deoxy-*N*-pentynyl glucosamine derivative resulted in the labeling of 99 proteins as compared to 367 proteins labeled

with the *N*-pentynyl glucosamine; 46 proteins were labeled with either reagent. This work supports the concept that the acetyl function from *N*-acetyl hexosamines can be transferred to a protein.

Metabolic labeling can be used for other biopolymers such as nucleic acids or proteins. DNA has been labeled with 5-ethynyl-2'-deoxyuridine (Lulai *et al.*, 2014) or 5-azidomethyl-2'-deoxyuridine (Neet and Luedtke, 2014); both of these compounds are analogues of thymidine (Figure 1) and can be coupled with fluorescent probes via click chemistry to permit identification. An approach related to metabolic labeling is the incorporation of unnatural amino acids with reactive groups (Liu and Schultz, 2010). The use of unnatural amino acids such as *p*-azidophenylalanine (Tian *et al.*, 2014) or alkene lysine analogues (Torres-Kolbus *et al.*, 2014) yield proteins with reactive site groups available for modification with probes.

Affinity Labeling

Both bioorthogonal labeling and activity-based probes are based, in part, on earlier work on affinity labeling of proteins (Wofsy *et al.*, 1962). The principle here is the specific binding of molecule to a protein which could, for example, be an enzyme or a receptor. The affinity label contains two parts: an

Figure 2 The evolution of affinity labels for sulfhydryl proteases.

affinity group which would bind to a specific site on a protein or other biopolymer and a reactive group such as an α -haloketo function. The reader is directed to a review on the design and use of affinity labels for additional information (Plapp, 1982). The reactive group should be sufficiently unreactive that reaction with a functional group such that proximity secondary to binding is the dominant factor. For example, consider the reaction of the cysteine residue in the enzyme active site of sulfhydryl proteinase with a peptide diazomethyl ketone where the rate of reaction can be as much as 10^{10} faster than reaction with free cysteine (Shaw and Green, 1981; Figure 2). Subsequent work showed that more complex peptidyl diazoethyl ketones could inactivate proteases (Savory *et al.*, 1993) but the reactions were quite slow. More recent work has used these observations to develop activity-based probes for identifying intracellular cathepsin activity (Falgout *et al.*, 2004). These investigators showed that BIL-DMK (biphenyl-leucine-diazomethylketone) inactivated purified cathepsins reacted with cathepsins in intact HepG2 cells. The insertion of a radiolabel into the reagent allowed identification of the modified proteins. Later work with this reagent demonstrated the distribution of the label in leukocytes populations in whole blood (Veilleux *et al.*, 2011).

Activity-Based Probes

Activity-based protein probes (Serim *et al.*, 2012) is a chemical biology approach based on covalent modifying extracellular and intracellular enzymes with probes which can be used to identify and isolate the active enzymes. The initial studies were performed on proteolytic enzymes and evolved from early work on affinity labels. The concept of activity-based probes depends on the relative inactivity of the zymogen or precursor forms of a proteolytic enzyme and the importance of functional group present at an enzyme active site. Diisopropylphosphorofluoridate (DFP) is a classic inhibitor of serine proteases such as trypsin and chymotrypsin. Liu *et al.* (1999) prepared a biotinylated derivative of DFP (Figure 3) which could be used to label and isolate serine proteases in crude tissue extracts. More sophisticated probes are diphenylphosphonate derivatives (Pan *et al.*, 2006) and di(chlorophenyl) phosphonate derivatives (Guarino *et al.*, 2014).

Activity-based probes have been developed for other enzymes such as kinases. Imbruvica[®] is a drug developed for the treatment of chronic lymphocytic leukemia (CLL) with the target being the covalent modification of Bruton's tyrosine kinase. Lanning *et al.* (2014) developed an alkyne derivative of ibrutinib (Imbruvica[®]) which could be used to detect Bruton's tyrosine kinase in cells (Figure 3). However, the first alkyne derivative was somewhat promiscuous as there are other protein sulfhydryl groups of sufficient reactivity and exposure to react with the Michael acceptor function. Decreasing the reactivity of the Michael acceptor improved the specificity of modification as there are undesirable side reactions observed with Imbruvica[®] (Levade *et al.*, 2014). This work provides an example of the use of chemical biology in drug development where quality is improved as a result of potential reduction of adverse reactions.

Figure 3 Activity-based probes. At the top is shown an activity-based probe for a serine protease while at the bottom is an activity-based probe for a tyrosine kinase.

Bioorthogonal Labeling

The development of the concept of bioorthogonal modification (Hang *et al.*, 2003; Bertozzi and Wu, 2013) has also been important in the maturation of chemical biology. A recent review (Patterson *et al.*, 2014) describes a number of chemistries available for bioorthogonal modification. The various techniques in chemical biology do overlap as the seminal paper on bioorthogonal labeling (Hang *et al.*, 2003) used metabolic labeling. The various tools in chemical biology do allow a study of proteins and other macromolecules inside the cell. The study of polysaccharides, both inside and outside the cell has been a particular challenge. It is therefore of no small importance that the signature paper (Hang *et al.*, 2003) on the use of bioorthogonal chemistry in cell biology involved the labeling of a O-linked mucin chain with an azide function (Figure 4) which could be subsequently tagged with a label such as a fluorophore. *N*-azidoacetylglucosamine was incorporated into the mucin chain in place of *N*-acetylglucosamine. Over the decade since this seminal work, there have been advances in chemistry with the use of a carbamate-linked cyclopropene function for a Diels-Alder condensation with a tag that, for example, contains biotin (Figure 4). The use of peracetylated derivatives enhances transport into the cell. This specific bioorthogonal labeling of polysaccharides permits imaging of glycans on cell surfaces (Stairs *et al.*, 2013); this study used orthogonal labels such as

Figure 4 Some examples of bioorthogonal reagents.

isonitrile and azide or cyclopropene and azide. A recent novel approach, described as ligand-directed tosyl chemistry (Tsukiji and Hamachi, 2014), permits the attachment of a probe such as fluorophore with a single reagent.

ω -Alkyn fatty acid derivatives are useful for localizing intracellular lipid-binding proteins (Raghavan *et al.*, 2008; Figure 4). An alkyne analogue of myristic acid has been prepared and has been demonstrated to couple to the N-terminus of a protein as coenzyme A intermediate (Host *et al.*, 2008; Thinon *et al.*, 2014). Bioorthogonal labeling of RNA has been accomplished by the incorporation of nucleobase analogues (Lulai *et al.*, 2014; Neet and Luedtke, 2014) or by post-synthetic modification (McDonald *et al.*, 2014).

Chemical Biology and Drug Development

Although the identification of the target of a drug is an essential part of the current drug development process, this was not so with earlier drugs such as aspirin where various therapeutic effects were discovered through use. The effect of aspirin on platelet aggregation was known before the discovery of the effect of aspirin on thromboxanes. Chemical biology now allows the study of the mechanism of action of drugs like aspirin in a rational manner. It is then of no small interest that there are chemical biology studies designed to define the mechanism of action of aspirin (2-(acetyloxy)-benzoic acid;

acetylsalicylic acid). Bateman *et al.* (2013) used an alkyne-aspirin derivative to identify aspirin targets in intact cells. Both the salicylate moiety and the 'active' acetyl group were known to be involved in pharmacological effects in inflammation and thrombosis, respectively. Recent studies have suggested that aspirin may have a function in reducing cancer mortality (Fraser *et al.*, 2014). Bateman *et al.* (2013) used 'click chemistry' to label intracellular protein targets of aspirin with a fluorescent tag (Figure 5). These investigators were able to demonstrate the modification of 120 proteins with this probe. Identification of the modified proteins may provide insight into the therapeutic targets of aspirin in cancer (Alfonso *et al.*, 2014). The work by Bateman *et al.* (2013) is another example of a bioorthogonal modification.

Chemical biology continues to develop as a sophisticated approach for the study of cellular physiology. The increasing sophistication of the structure of the probes will increase specificity of labeling. The use of Raman spectroscopy and near-infrared spectroscopy will eliminate the necessity of attaching a reporter group. The most exciting potential is the elucidation of the mechanism of action of therapeutics. The aspirin story is discussed above and it is likely that the bioorthogonal labeling of target protein by aspirin-based reagents will elucidate the putative role of aspirin in cancer. Recalling that aspirin developed from the use of willow bark as an analgesic and anti-inflammatory therapeutic, it would be useful to prepare bioorthogonal reagents based on emerging

Figure 5 The development of a bioorthogonal reagent based on aspirin.

herbal therapeutics (Gannier *et al.*, 2007) to determine their target(s).

Glossary

Active pharmaceutical ingredient (API) The final product in the manufacturing process prior to formulation. API may also be known as the active ingredient.

Click chemistry A general term describing a simple chemical reaction joining two molecules; the term is used most frequently to describe alkyne–azide cycloadditions.

Comparative molecular field analysis (CoMFA) Extends the quantitative structure activity relationship (QSAR) analysis into three dimensions by establishing a relationship between biological activity and the electronic properties of the chemical in three dimensions; a quantitative consideration of electronic and physical shape of a chemical. CoMFA can be an analytical tool to rationalize observed activity or to predict the activity of a new compound.

Complementary determining region The specific region in the Fab domain (Fv) of an antibody molecule which recognizes the antigen. The complementary determining region may also be referred to as the paratope.

Drug substance The formulated form of the active pharmaceutical ingredient which is the material given to a patient. The drug substance may also be known as the drug product or dosage form.

Epitope That portion of an antigen which is recognized and bound by the paratope on the antibody. An epitope may be continuous in that it is a linear sequence of amino acids or other monomer unit or discontinuous in that the epitope is contributed by residues from disparate regions of a polymer which is the antigen.

Formulation The process by which the active pharmaceutical ingredient is converted into the drug substance and may involve the addition of active or inactive ingredients. The addition of active ingredients may result in a product being designated as a combination product. Inactive ingredients generally referred to as excipients are added to improve the properties of the drug substance.

Fusion protein A protein where two different proteins or two distinct protein domains are expressed as a single protein encoded by the joining of the respective DNA sequences. Fusion proteins may also be referred to as chimeric proteins.

Hammett equation A metric developed by Louis Hammett to predict reaction rates based on two constants, σ which is unique to a chemical group such as chloro group or

nitro group and ρ which was a descriptor of the nature of the reaction, solvent, and temperature.

High-throughput screening The process by which a lead compound may be developed into an active pharmaceutical ingredient. Large numbers of structural variations of the lead compounds are evaluated for biological activity either in silico or by evaluation of physical binding to a target using solid-phase (microplate) technology.

Hit A term used in high-throughput screening to describe a compound with improved properties which will be further developed in the search for a lead compound.

Lead compound A chemical compound which has the desired pharmacological effect but is unsuitable to serve as a drug. The lead compound provides the base structure which is then modified by organic chemistry or enzymes to provide the active pharmaceutical ingredient.

Log *P* A partition coefficient derived from the ratio of concentration of an organic compound, frequently a drug, in water and an organic phase, usually *n*-octanol. Log *P* increased with the lipophilic nature (hydrophobicity of the compound).

Payload A term used to describe the drug component of an antibody–drug bioconjugate.

Quality-by-design A systematic approach to the development of a product with specific predefined objectives. An emphasis is placed on the understanding of the product, understanding of the process, and understanding of process control based on sound science and quality management.

Quantitative structure activity relationship (QSAR) An analytical technique which uses the Hammett constant σ in combination with a constant, π , which is a measure of the lipophilicity of the compound, and steric component. The success of QSAR depends on the quality of the descriptors used for the model building. The initial work on 2D-QSAR was extended to 3D-QSAR by CoMFA which allows the consideration of shape (electronic and physical). Structure-based 3D-QSAR can be used when the structures of the ligand and the receptor are known while ligand-based 3D-QSAR is used when only ligand structure is known.

Structural biology The study of macromolecular structure and supramolecular structure. Objects of interest range from proteins to organelles such as mitochondria and ribosomes. Techniques include computational biology, crystallography, nuclear magnetic resonance, and electron microscopy.

Introduction

The term drug is used broadly within this article. Regulatory agencies such as the Food and Drug Administration (FDA) separate drugs from biologics on a somewhat arbitrary basis.

Drugs are usually low-molecular weight compounds prepared by organic chemical synthesis. Drugs are classified on the basis of solubility and permeability using the biopharmaceutical classification system (BCS) (Benet, 2013). Biologics include gene therapy, cellular therapy products, and proteins that are

isolated from a biological source such as blood plasma. Recombinant deoxyribonucleic acid (DNA) technology yields proteins that are therapeutics manufactured by fermentation in bacterial cells or cell culture in mammalian cells. More recently drugs have been coupled to monoclonal antibodies to create conjugate drugs most commonly known as antibody–drug conjugates. Drugs can also be linked to other biologicals to create bioconjugate drugs (Nielsen *et al.*, 2014). Fusion proteins which combine a therapeutic protein with a protein which influences pharmacokinetic behavior are also within the purview of drug design; an example is provided by the fusion of the carboxyl terminal region of the immunoglobulin protein (Fc domain) with factor VIII to provide a product with an extended half-life (Shapiro, 2013). Products obtained from recombinant DNA technology are considered to be drugs for regulatory purposes. The term biopharmaceutical can be used to describe both drugs and biologics.

The term target is used to describe the site of action of a drug. Drugs are most commonly directed at the inhibition of enzymes or receptors and more recently have been directed at protein-binding sites with the goal of disrupting protein–protein interactions. Another class of drugs are replacements rather than inhibitors; two examples are insulin and growth hormone, two peptide hormones, which were approved as drugs and not biologics. More recently, advances in structural biology enable the visualization of binding sites on proteins permitting computer design of drugs based on fit into a space on the target protein as was done for HIV-1 (human immunodeficiency virus type 1) protease and haloperidol (DesJarlais *et al.*, 1990). These investigators used a computer to make a negative image of the enzyme active site much in the way one would make a plaster cast of a footprint in the ground. A database was then used to find a chemical which would best fit in the computer-derived enzyme active site cavity. The program identified bromperidol as a good steric fit and haloperidol, an approved antipsychotic drug, that served as lead compound for further testing.

Implicit in the term drug is the understanding that this is a substance that will be used to effect a physiological change in the recipient. Legal drugs required a regulatory pathway that has little to do with the science employing concepts such as quality-by-design (QbD) (Rathore and Winkler, 2009; Martin-Moe *et al.*, 2011). It is imperative that good records are maintained from the start of a project such that rational development of the final drug product can be validated.

History of Drug Development

The current process of drug design and development (Figure 1) is a complex process with considerable regulatory oversight. However, over the course of history, drugs were first identified by the observation of the effects that various natural products had on sick and healthy people. The use of willow bark to relieve pain dates back to thousands of years and was shown to be dependent on its content of salicylates (Vane, 2000). Identification of salicylate as the active component of willow bark provided one of the first ‘lead compounds’ (salicylic acid) for drug development resulting in the discovery of aspirin (Sneider, 2000). The fortuitous discovery of useful

Figure 1 The process of drug development.

drugs remained valuable for the pharmaceutical industry over the centuries with more recent examples such as disulfiram (Kragh, 2008) and Viagra[®] (Campbell, 2000). In the case of disulfiram, it was careful consideration of laboratory data for unexpected results and with Viagra[®], it was the careful study of all results from an otherwise unsuccessful clinical study.

Evolution of Drug Design

Drug design is more complex than just the development of the pharmacologically active compound. A lead compound frequently needs to be chemically modified, for example, to eliminate undesirable side effects or improve pharmacokinetic behavior. In the case of aspirin (Figure 2), salicylic acid was considered the active ingredient for pain but caused gastric irritation; acetylation of the *o*-hydroxyl group provided the therapeutic derivative used today. While some aspects of the mechanism of action of aspirin are understood, such as acetylation of target proteins, some newly identified applications in cancer therapy remain poorly understood (Madhi *et al.*, 2006). Another example of the evolution of a natural product to a drug is provided by physostigmine (Figure 2). Physostigmine (eserine) was identified as the active component of the Calabar bean (Esere nut; *Physostigma venenosum*) found in tropical Africa. It was known to contain a potent poison. Work some 60 years ago (cf. Goldstein, 1945) demonstrated that physostigmine was a competitive inhibitor of acetylcholine esterase. The early work established physostigmine as a lead compound for a class of cholinesteric drugs resulting in novel

Figure 2 Lead compounds from nature to drug products.

derivatives such as phenserine which is under consideration for use in Alzheimer disease (Reale *et al.*, 2014; Figure 2). Another example is provided by thrombin, the final enzyme in the process of blood coagulation. Knowledge of the importance of guanidine group in substrates resulted in the preparation of a number of compounds which never became good drugs. Improvements in our understanding of thrombin have resulted in the development of new drugs which are in fact pro-drugs such as dabigatran etexilate which inhibit thrombin after hydrolysis by an esterase (Figure 3). As development has proceeded from lead compounds, specificity and avidity increased resulting in a more effective drug. Current drug development uses techniques of structural biology, high-throughput screening (HTS), and virtual screening, or computer modeling.

Structural Biology and Drug Development

The use of structural biology in the development of inhibitors for HIV protease was mentioned above. This is an example of rational drug design. Rational drug design is a method for identifying new drugs based on knowledge of the three-dimensional structure of the target protein (Hardy *et al.*, 1987). Knowledge of the three-dimensional structure provides information on the binding sites of substrates and inhibitors in the case of enzymes, agonists, and antagonists. Computer programs then optimize the binding characteristics of various

Figure 3 Aryl guanidines – from lead compounds to active pharmaceutical ingredient for use as thrombin inhibitors.

compounds yielding candidates which are then evaluated in *in vitro* assay systems for potential therapeutic effectiveness. Knowledge of the target structure is essential for docking studies; knowledge of protein structure is critical for protein modeling. Structural biology is frequently considered an activity within chemical biology.

HTS

HTS is another approach for identifying potential drug candidates. The success of HTS is dependent on the identification of meaningful assay systems. One example is the development of peptide substrates for the measurement of IgA1 protease activity in a 386-well microplate assay system (Choudary *et al.*, 2013). Microplate formats now range from 4 wells/plate to 1536 wells/plate; most HTS procedures use 96 well plates, 386 well plates, or 1536 well plates. The use of higher density plates greatly increases screening output; use of a 96-well plate allows 10 000 compounds to be screened per day, 40 000 compounds per day with a 384-well microplate, and 200 000 compounds per day with a 1536-well microplate.

Other solid phase assay formats can also be used, such as microfluidic chips for cell-based screening systems (Young, 2013). The process of HTS is costly and can be labor-intensive depending on the extent to which robotics are used in the process. A relatively new approach to HTS is fragment-based screening (Schulz and Hubbard, 2009) which involves a smaller library of small molecules which are evaluated for the binding to a target. Fragments which bind are then assembled

into larger compounds which are then evaluated for binding to a target.

Virtual Screening

The magnitude of potential drug compounds estimated to be 10^{17} (Valler and Green, 2000) requires the automation of drug design such that even with high density plates and combinatorial synthetic methods, screening of libraries in excess of a million compounds is a formidable task. The basis for virtual screening depends on the establishment of quantitative structure activity relationships (QSAR). QSAR is a modeling technique used to predict the activity of a chemical from molecular characteristics known as descriptors (Goodarzi *et al.*, 2012). QSAR models are also used to predict chemical toxicity (Benigni and Richard, 1998). QSAR modeling can be traced to the work of Hammett (1937). Hammett was able to separate the effect of a substituent on benzene ring on the rate of reaction into a constant, σ (sigma) which is a function of the substituent group and ρ (rho) which is the reaction constant dependent on the nature of the reaction, solvent, and temperature. Approximately 30 years later, Hansch, Fujita, and coworkers (Hansch *et al.*, 1962) took the Hammett constant, σ , and combined it with a measure of lipophilicity, π (pi), which is derived from $\log P$ ($\log P$ is the logarithm of the distribution of the compound in question between *n*-octanol and water) measurement and developed a new method for predicting correlation between biological activity and chemical structure. This work with that of others evolved into QSAR (Hansch, 1976). Comparative molecule field analysis (CoMFA) can be considered an extension of QSAR from 2-D to 3-D emphasizing the importance of molecular shape on biological activity (Cramer *et al.*, 1988). Virtual fragment-based screening is also being used to develop lead compounds through docking programs (Cavasotto and Orry, 2007). Regardless of the success of virtual screening, there will be an eventual need to document the value of a lead compound before proceeding to drug development (Funatsu *et al.*, 2011). Virtual screening can also be used to predict ADME (absorption, distribution, metabolism, excretion) properties (Hop *et al.*, 2008).

Classical HTS screening and computer-assisted drug design should result in the same candidate product as was demonstrated with an inhibitor for transforming growth factor β type I receptor kinase. One group used the HTS technique (Sawyer *et al.*, 2003) while the other group (Singh *et al.*, 2003) used 'shape-based' screening which uses docking programs and virtual screening for optimization of a starting chemical which had activity. A more complete description of the factors driving the congruence of these two is available (Shekhar, 2008).

Drug Design and Biologics

It has been possible to use drug design in the development of biologics, specifically antibodies. Haber (1983) was one of the first to consider antibodies as drugs which would be amenable to rational drug design. The use of polyclonal immunoglobulin as a therapeutic product dates to the 1940s with the

development of the Cohn fractionation scheme for blood plasma. Some 40 years later, it became possible to prepare monoclonal antibodies which would be specific for a specific epitope on a target. Various monoclonal antibodies have become therapeutic products such as Herceptin[®] or Avastin[®]. The classical development of monoclonal antibodies is a tedious process and there has been considerable interest in using similar techniques to those developed for small molecules for the development of specific monoclonal antibodies. The objective here is to model the site on the antibody, the complementary determining region (CDR) or paratope which combines with the epitope or antigenic determinant. So the challenge here is two-fold compared to the docking experiments described above for small molecules in that the structures of two large proteins are required.

An antibody such as immunoglobulin G (IgG) is a large protein which can, for the purpose of the current discussion, be divided into two parts (Figure 4). Antibody-drug design has focused on the amino terminal region (Fab domain) portion of the protein as it is the region of the protein that recognizes the antigen and it is possible to use limited proteolysis to obtain the Fab fragment suitable for study by structural biology. In particular, it has been possible to obtain a high-resolution crystal structure for Fab-antigen complexes such as that for the Fab derived from a monoclonal antibody and the α -toxin from *Staphylococcus aureus* (Oganesyan *et al.*, 2014). This monoclonal antibody (MED14893) is being developed as a therapeutic agent for diseases mediated by *S. aureus* such as soft tissue infections and sepsis. The structure demonstrated that the antibody recognized a novel epitope and prevented the α -toxin from forming a lytic conformation. Only a portion of the Fab region is thought to bind the antigen; this is the variable fragment (Fv) region which is composed of the amino terminal regions of the heavy and light chains and contains the CDR or paratope region. Work has progressed on the modeling of Fv fragments where the predicted structure of the Fv domain is compared to those obtained by crystallography (Teplyakov *et al.*, 2014). The rapid progress in this area suggests that ability to design antibodies as drugs will increase in the next decade; challenges will

Figure 4 The structure of an immunoglobulin antibody showing the several functional domains.

Figure 5 The structure of an antibody–drug conjugate.

remain driven, in part, by the discontinuous nature of epitopes (Kuroda *et al.*, 2012).

Antibody–Drug Conjugates

One of the several problems in drug design is the delivery of the drug to the site of action without collateral damage. Many anticancer drugs are cell poisons and do not discriminate between healthy cells and tumor cells. In addition, many drugs are complex chemicals requiring many synthetic steps and the manufacturing process is expensive. Coupling of the drug to a monoclonal antibody directed toward the target cell has evolved as a novel approach to this problem (Leal *et al.*, 2014). In principle this approach allows the delivery of an inactive drug to the target cell where the antibody–drug conjugate is internalized and transported to the lysosome where the active drug is released (Figure 5). The coupling of the drug to protein uses a linker usually attached to a maleimide which will selectively react with cysteine residues on the antibody protein. Conjugate vaccines consisting of a polysaccharide antigen linked to a protein carrier are also used. Coupling of polysaccharides to protein carriers such as tetanus toxoid protein usually used periodate oxidation of the carbohydrate with subsequent coupling to lysine residues in the protein (Frasch, 2009).

Introduction

The discovery of hybridoma technology by G. Kohler and C. Milstein in 1975 heralded a new era in antibody research and clinical development (Milstein, 2000). These murine hybridomas provided the first reliable source of monoclonal antibodies (IgG; Figure 1). Initially, antibodies were developed for *in vitro* diagnosis of blood components and disease-associated biomarkers (immunoassays and enzyme-linked immuno-sorbent assays (ELISA)). Later, antibodies became the core detection system for immunohistochemistry (IHC), predominantly for detection of cancer in tissue biopsies. Throughout the 1990s, innovative recombinant DNA technology (chimerization and humanization) successfully reduced the immunogenicity of injectable (*in vivo*) murine antibodies thereby enhancing clinical efficiency and leading to a number of therapeutic IgG and antibodies and their smaller fragments (Fab, scFv molecules). These developments have continued and since 2000 over 30 injectable antibodies against cancer, viral, and inflammatory diseases have been approved. Most recently, innovative structural designs have

further improved *in vivo* pharmacokinetics, expanded immune repertoires and enabled screening against refractory targets and complex proteome arrays, while novel molecular evolution strategies have enhanced affinity, stability, and expression levels. This article discusses the creation of a vast range of novel, engineered, antibody-based reagents which specifically target biomarkers of human health and disease. Beyond 2015, an international collaboration will make antibodies available against every human protein, analyzed for expression in normal and diseased tissue, for research, diagnosis and eventually for improved therapy (the Human Protein Atlas; Fagerberg *et al.*, 2014).

Antibodies for *In Vitro* Diagnosis, in Soluble (RIA), Surface-Bound (ELISA), Cell-Bound (Fluorescence-Activated Cell Sorting (FACS)), Tissue-Bound (IHC) and Modern E-Device Formats

Antibodies are the backbone of the immunodiagnostics industry, providing high-affinity reagents with precise target

Figure 1 Intact antibody (IgG) and engineered formats. Schematic representation of an intact IgG together with Fab and Fv fragments and single V-domains and C-domains. V-domains are depicted as colored ovals with a dot representing the antigen-binding site and C-domains are uncolored ovals. Engineered recombinant antibodies are shown as scFv monomers, dimers (diabodies), trimers (triabodies), tetramers (tetrabodies) with linkers joining the V-domains represented as a black line. Minibodies are shown as two scFv modules joined by two C-domains. Also shown are Fab dimers (conjugates by adhesive polypeptide or protein domains) and Fab trimers (chemically conjugated). Colors denote different specificities for the bispecific scFv dimers (diabodies) and Fab dimers/trimers.

specificity for the detection of biological molecules (e.g., disease biomarkers) and chemical molecules (e.g., blood components and toxins). The detection output can range from a simple colorimetric Yes/No score (e.g., pregnancy testing in urine samples using dip-sticks) to accurate high-throughput quantitation (e.g., multi-channel analytical instrumentation for full-component blood analyses). Antibodies are extremely stable proteins and can be stored for years, either in solution or immobilized on diagnostic devices. Initially, antibodies were tagged with radioactivity to measure target binding (radioimmunoassay (RIA)) but this has been superseded by fluorescent and luminescent probes for accurate laser-driven quantitation, or enzyme amplification for improved sensitivity. For example, in the commonly used ELISA format, after the initial antibody binding to target, an enzyme is used to generate and amplify a color or fluorescent or electrochemical signal. For rapid, inexpensive, home-based testing, antibodies are immobilized on membrane devices and in 'sandwich' ELISA format, used to detect agents in saliva or blood (pin-prick) or, for example, in urine for pregnancy testing. The ELISA process can be scaled up in microarray (tray) formats or automated for high-throughput diagnosis with robotically driven spectrophotometric or laser detectors. In the USA alone, the \$80 billion diagnostic-lab industry performs nearly 10 billion tests annually and is estimated to provide the basis for about 70% of doctors' medical decisions. Speed and sample size is critical, and new technologies for complete blood diagnosis from a single blood pin-prick sample are in development (TheranosTM). In the most recent developments, antibodies can now be attached to multiple bead populations (or nanoparticles) differentiated by size and levels of fluorescence excitation to simultaneously quantitate multiple analytes in a single assay. In similar technology, DNA 'barcoded' antibodies have been developed with simple amplification systems for extreme-sensitivity, multitarget diagnosis (Agasti *et al.*, 2012).

One of the most widespread diagnostic applications has been the detection of target antigens in tissue sections (IHC; Figure 2). In this method, the initial antibody binding to the antigen is followed by an enzyme-driven color deposit and used for accurate diagnosis (Figure 2). In a further advance, fluorescently tagged antibodies can be used to selectively bind ('paint') a unique cell type in a complex cell mixture. Flow cytometers are then used to accurately assess the quantity and antigen-type displayed on the tagged cells in the mixture, using the unique surface fluorescence provided by the antibody. In cell-sorting (FACS) formats, the tagged cells can be separated from the untagged cells, for more detailed examination of these minor cell populations. Single cells can be isolated from extremely complex biological mixtures, providing exquisite diagnosis of cell physiology and phenotype.

Antibodies for *In Vivo* Applications: Immunotherapy with Humanization and Deimmunisation

Intact multivalent antibodies (IgG; Figure 1) provide high-specificity, high-affinity targeting agents for immunotherapy and currently provide over 40% of \$80 billion per annum biopharmaceutical industry (Weiner *et al.*, 2012; Reichert,

Figure 2 Cancer diagnosis by Immunohistochemistry (IHC). Antibodies are the core reagents for the detection of tumor-associated antigens in tissue sections of cancer biopsies. Shown below is the TAG-72 tumor antigen, expressed in adenocarcinoma of the prostate and identified by a murine CC49 antibody specific to TAG-72. For detection, a second antibody carrying peroxidase is used to bind to the CC49 murine antibody and the peroxidase used to develop a brown stain. Note the presence of secreted antigen (dark brown) and cell-associated antigen (light brown), against a background of clear benign (noncancerous) tissue. Prostate cancer tissue was positive for TAG72 (dark areas) while benign tissue was negative (light areas).

2014). Their simultaneous binding to two antigens increases functional affinity and confers high retention times on target molecules. In addition, intact antibodies comprise Fc domains which can be important for cancer immunotherapy by both recruiting cytotoxic effector functions and extending the serum half life, mediated by the Fc receptor. Unmodified murine monoclonal antibodies formed the first wave of approved immunotherapeutic reagents, although their *in vivo* applications were limited since repeated administrations provoked an anti-mouse immune response. Simple strategies have been developed to avoid, mask or redirect this human immune surveillance, including fusion of murine variable regions to human constant regions as 'chimeric' antibodies, or 'deimmunizing' by removal of T-cell epitopes or 'humanizing' by grafting murine surface residues onto human acceptor frameworks. Modern alternative strategies now allow selection of fully human antibodies directly from natural or synthetic repertoires, including live transgenic mice producing purely human antibodies.

Design of 'Antibody Fragments' for Unique Clinical Applications *In Vivo*

For cytokine inactivation, receptor blockade or viral neutralization, the Fc-induced effector functions are often unwanted and can be simply removed by proteolysis of intact antibodies to yield monovalent Fab fragments. Proteolysis, however, does not easily yield molecules smaller than a Fab fragment, and microbial expression of single-chain Fv (scFv) is currently the favored method of production (Figure 1). In scFvs, the variable (V_H and V_L) domains are stably tethered together with a flexible polypeptide linker (Figure 1; Holliger and Hudson, 2005).

In comparison with whole antibodies, small antibody fragments such as Fab or scFv exhibit improved pharmacokinetics for tissue penetration and also provide full binding specificity since the antigen-binding surface is unaltered. However, Fab and scFv are monovalent and often exhibit fast off-rates and poor retention time on the target. Therefore, Fab and scFv fragments have been engineered into dimeric, trimeric, or tetrameric conjugates to increase functional affinity, employing either chemical or genetic cross-links (Figure 1). Various methods have been devised to genetically encode multimeric scFv, with the most successful design being the simple reduction of scFv linker length to direct the formation of bivalent dimers (diabodies, 60 kDa), triabodies (90 kDa), or tetra-bodies (120 kDa) (Figure 1). Indeed, the first clinical imaging trials of scFv fragments are likely to be as multivalent reagents (diabodies and minibodies), since they exhibit high functional affinity and have been very successful in preclinical studies (Knowles and Wu, 2012; Li *et al.*, 2010, 2011).

Pharmacokinetics of Intact Antibodies versus Fragments

The efficiency of antibodies *in vivo*, for example, in cancer therapy, lies in their capacity to discriminate tumor-associated antigens at low levels. Immunotherapy has been more successful against circulating cancer cells than solid tumors due to the better cell accessibility, and delivery of therapeutic payload. The lymphoma-associated antigens CD30 (Hodgkin's) and CD20 (Non-Hodgkin's) have been successfully treated by therapeutic antibodies.

Radiolabelled antibodies are important clinical reagents for both tumor imaging and therapy. The choice of radionuclide dictates the application, for example, 124-Iodine is used for positron emission tomography (PET) imaging and 123-Iodine for single-photon emission computed tomography (SPECT). Therapeutic administration using for example 90-Yttrium requires a balance between long dissociation rates at the target site and slow blood clearance which can lead to liver accumulation and high radiation exposure of other tissues. Bio-distribution studies in solid tumors have also revealed that large size of IgG molecules (150 kDa) can inhibit rapid tumor penetration, whilst intermediate sized multivalent fragments providing rapid tissue penetration, high target retention, and rapid blood clearance (Knowles and Wu, 2012). For example, diabodies (60 kDa) are ideal with short-lived radioisotopes for clinical imaging due to the fast clearance rates. Larger molecules such as PEGylated diabodies (80 kDa), are used with long-lived radioisotopes and are ideal for tumor therapy since they achieve a higher total tumor 'load' (Figure 3; Li *et al.*, 2010, 2011). Minibodies (90 kDa) and Fab dimers (110 kDa) are also useful for tumor imaging (Knowles and Wu, 2012).

High-affinity antibodies ($K_d < 10^{-10}$ mol l⁻¹) may not be the best reagents for *in vivo* applications, since they bind tightly to first-contact tumor cells and can fail to fully penetrate solid tumors (Adams *et al.*, 2001). High-affinity antibodies can also form large immune complexes with soluble antigen leading to significant off-target toxicity. Intermediate-affinity antibodies ($K_d \sim 10^{-8}$ mol l⁻¹) are potent tumor-loading agents more

resistant to immune complex formation (Cao *et al.*, 2012). Note that affinity is an exceptionally important consideration when evaluating the design and efficacy of targeted therapeutics.

The short half life of antibody fragments can also be extended using modification with polyethylene glycol, which avoids both renal and hepatic localization. The improved functional affinity, tumor penetration, and biodistribution of these novel engineered antibody fragments herald the development of a new generation of reagents for both imaging and therapy.

Engineering Multiple Specificity in Antibody Fragments

Bispecific Antibodies

Bispecific antibodies contain two different binding specificities fused together and, in the simplest example, bind to two adjacent epitopes on a single target antigen, thereby increasing the avidity. Alternatively, bispecific antibodies can cross-link two different antigens and are powerful therapeutic reagents, particularly for recruitment of cytotoxic T cells for cancer treatment. For example, CD19 on a cancer cell can be cross-linked to CD3 on a T-cell, thereby recruiting T cells to attack and kill the cancer cell. Bispecific antibodies and also dimeric ScFv fragments and bispecific diabodies have been produced for this purpose (Figure 1; Maher and Adami, 2013).

Bifunctional Antibodies

The original 'Magic Bullet' concept has proven a success; antibodies have been fused to a vast range of molecules that ascribe important ancillary functions following target binding. These include radionuclides (discussed above) and also cytotoxic drugs, toxins, peptides, proteins, enzymes, and viruses, the latter for targeted gene therapy. For cancer therapy, bifunctional antibodies are engineered to effectively target tumor-associated antigens at low levels and then deliver a cytotoxic payload to tumor cells. The latest antibody-toxin conjugates are stable *in vivo*, minimally immunogenic and are proven cancer therapies; AdcetrisTM for Hodgkin's lymphoma and KadcylaTM for Her-2 positive breast cancer (Panowski *et al.*, 2014). These antibody-drug conjugates (ADCs) carry only a few drug molecules on each antibody. As nanoparticle conjugates and immunoliposomes, antibodies have been shown to deliver higher drug payloads than simple chemical fusion of the drugs to the antibody. Antibody-enzyme fusions have also been developed for prodrug activation, primarily for cancer therapy.

Antibody Libraries: Construction, Display, and Selection

Library display has superseded hybridoma technology through the creation of large natural and synthetic antibody repertoires *in vitro*. From these novel libraries, specific high-affinity antibodies can be selected by linking phenotype (binding affinity) to genotype, thereby allowing simultaneous recovery of the

Figure 3 Molecular Imaging using antibodies targeting human tumors (xenografts, growing in mice). Diabodies with and without conjugated PEG, were labeled with 64-Copper and PET (positron emission tomography) images taken at 1, 4, 22, and 46 h. Without PEG the diabodies are filtered through the kidney (orange arrows), but with added PEG, kidney uptake is avoided and the diabody loads almost exclusively into the xenograft tumor (blue arrows), achieving high-contrast tumor imaging at a remarkable 70% ID/gram tumor uptake. Reproduced from Li, L., Turatti, F., Crow, D., *et al.*, 2011. Site-specific conjugation of monodispersed DOTA-PEGn to a thiolated diabody reveals the effect of increasing peg size on kidney clearance and tumor uptake with improved 64-copper PET imaging. *Bioconjugate Chemistry* 22, 709–716; and Li, L., Crow, D., Turatti, F., *et al.*, 2010. Monodispersed DOTA-PEG–conjugated anti-TAG-72 diabody has low kidney uptake and high tumor-to-blood ratios. *Journal of Nuclear Medicine* 51, 1139–1146.

gene encoding the selected antibody. Antibodies are usually displayed as monovalent Fab or scFv fragments and then, as required, reassembled into intact immunoglobulin (Ig) or multivalent variants following selection. If the repertoire is sufficiently large, a high-affinity Fab or scFv can be selected directly or, more frequently, the recovered gene is subjected to cycles of mutation and further selection to enhance affinity (Harel Inbar and Benhar, 2012).

Bacteriophage Display

Fd-phage and phagemid technologies are currently the most popular *in vitro* methods for the display of large repertoires and for the selection of high-affinity recombinant antibodies against a range of clinically important target molecules. Important improvements in selection technology have included array screening for high-avidity antibodies and recovery of internalized phage from live cells to select against internalizing (human) receptors, which are useful for ADC therapeutic designs.

Cell-Surface Libraries

Antibodies had been displayed on the surface of cells (yeast or bacterial cells) enabling efficient screening by high-speed flow cytometers to identify high-affinity antibodies.

Transgenic Mice

Transgenic mice have been produced that lack the native murine immune repertoire and instead harbor most of the human antibody repertoire in the germline. Injection of antigens into these humanized animals leads to the development of human-like antibodies which have undergone murine somatic hypermutation and selection to relatively high affinity. Recovery of antibodies can be by classic hybridoma technology or, for more efficient affinity enhancement, can be recovered by the *in vitro* display and selection technologies.

Maturation

Transgenic mice and display libraries typically produce human antibodies with affinities in the range from 10^{-7} to 10^{-9} M. Obtaining higher affinity antibodies is crucial for efficient binding to the antigenic target for *in vitro* diagnosis, viral neutralization, cell targeting, and *in vivo* imaging. To improve antibody affinity, various *in vitro* strategies have been developed to mimic the mammalian *in vivo* process of somatic hypermutation, focusing on several cycles of mutation, display, selection (recovery), and gene amplification. Affinity enhancement can be restricted to mutations in the

antigen-binding surface (complementarity determining regions (CDRs) loops) but even with the most detailed structural information, the techniques for design of precisely complementary surfaces via interface mutations remain in their infancy. Importantly, mutations in the underlying framework regions have frequently provided large increases in affinity, stability, and expression.

Production, Stability, and Expression Levels

Production of antibodies for preclinical and clinical trials has been evaluated in numerous expression systems including bacteria, yeast, plants, insect, and mammalian cells. Bacteria are favored for expression of small, non-glycosylated Fab and scFv fragments, usually with terminal polypeptides, such as c-myc, His, or FLAG for affinity purification. Mammalian cells are favored for intact antibodies and occasionally, also for expression of scFvs, diabodies, and minibodies.

High-Value Clinical Applications

Cancer targeting for delivery of radioisotope or cytotoxic drug payloads has been discussed earlier, and this section describes some other clinical applications of engineered antibodies for viral infection, autoimmune disease, stroke, neurodegenerative diseases, and image-guided surgery.

Pathogen Neutralization, Antiviral Therapy, and Vaccines

Antibody binding can directly and effectively block the activity of many pathogens without requiring Fc-mediated cytotoxicity. Indeed, this has always been the promise of antibody-mediated viral neutralization and the first monoclonal antibody (Palivizumab; SynagisTM) for the treatment of viral disease was launched in 1998. Palivizumab is a humanized antibody used in immunoprophylaxis for the prevention of severe respiratory syncytial virus (RSV) disease. Despite this success, and the huge range of antibodies available against human immunodeficiency type 1 (HIV) and hepatitis C (HepC), the use of recombinant antibodies as therapeutics against viral infection has been limited. Only a few rare antibodies have exhibited potent neutralization *in vitro* and antiviral efficacy in animal models (Koff *et al.*, 2013). This is probably due to viral efficiency both in producing escape mutants and in evolving antibody-resistant receptor-binding surfaces.

At the crux of immune modulation, vaccines have also been effective for producing effective, host-derived antibodies against a number of major diseases (polio and cholera). In response, many pathogens have evolved effective evasion mechanisms to avoid host immuno-surveillance. A promising new strategy is to use antibodies as Trojan horses to drive immunogenic epitopes and molecular motifs directly into dendritic cells and force the host to produce a more effective immune response (Sehgal *et al.*, 2014). This re-booting or boost to the natural immune effector mechanism has worked in animal models and is being applied to clinical diseases (Koff *et al.*, 2013).

T-Cell Targeting and Immune Checkpoint Inhibitors

Cancer cells can be destroyed by cell recruitment of cytotoxic T cells, natural-killer (NK) cells or macrophages which can themselves be targeted by encoding cell-surface antibodies (usually scFv). The latest strategies involve removal and then genetic engineering a patient's T-cells to produce chimeric antigen receptors (CARs), which then efficiently target tumor when re-infused into the patient. Alternative cell recruitment strategies include using bispecific antibodies to cross-link and activate effector cells at the tumor site, or the use of bifunctional antibodies fused to cytokines and chemokines to provide local T-cell stimulation and proliferation, also at the tumor site (Hess and Neri, 2014).

Immune checkpoint-blocking antibodies modulate T-cell pathways that regulate T cells and have the potential to re-invigorate an antitumor immune response (Kyi and Postow, 2014). Ipilimumab (YervoyTM) was the first US Food and Drug Administration (FDA)-approved immune checkpoint antibody licensed for the treatment of metastatic melanoma (MM) and blocks a checkpoint molecule CTLA-4 (cytotoxic T-lymphocyte antigen 4). The Programmed Death receptor (PD-1) has also been effectively targeted by systemically administered antibodies, reducing the effect of the tumor-associated PD-L1 and enhancing T-cell responses to mediate antitumor activity. While both CTLA-4 and PD-1 function as negative regulators, CTLA-4 attenuates the early activation of naïve and memory T cells whilst PD-1 is primarily involved in modulating T-cell activity in peripheral tissues via interaction with its ligands, PD-L1, and PD-L2. Unfortunately, not all patients respond to these therapies, and evaluation of the optimal clinical strategy continues. These immune checkpoint inhibitors may also have profound effects in ameliorating stroke (Bodhankar *et al.*, 2014).

Angiogenesis and Vascular Blockade/Transport

Blocking angiogenesis (blood vessel growth) to prevent the establishment and expansion of tumors is becoming an important strategy in the fight to reduce cancer spread. Bevacizumab (AvastinTM) targets VEGF, blocks angiogenesis and is an FDA-approved therapy for several metastatic cancers. Indeed, some of the anti-angiogenic antibodies act synergistically to enhance the efficacy of tumor-targeting antibodies and may become more highly efficient therapeutics when used in combination (Yasuda *et al.*, 2013).

To tackle neurodegenerative diseases, antibodies, and engineered fragments have been designed to transport through neural vasculature thus crossing the blood-brain barrier to target their activity within plaques to inhibit or ameliorate misfolded protein aggregates (Pardridge, 2014).

Image-Guided Surgery: From Radioactive Image-Guided Surgery (RIGS) to Fluorescence Image-Guided Surgery (FIGS)

Antibody-guided imaging can detect cancer in real-time during surgery, providing more accurate cancer treatment while sparing healthy tissue. Antibodies were first used as

radioimaging probes to detect and pinpoint tumor lesions to guide surgical excision. Relying on PET and SPECT whole-body cameras, this RIGS procedure was too lengthy for practical use and has now been replaced by antibodies conjugated to fluorescent or luminescent tracers to can effectively 'paint' tumors or diseased lesions (FIGS; Keereweer *et al.*, 2013). Using rapid detection by externally-guided optical-probe technology (otoscopes) which can be directly coupled to robotic surgical instruments, real-time guided dissection is now possible. Once detected by FIGS, tumors can also be ablated by new high-precision external beam radiotherapy.

Conclusion

Antibodies and their engineered fragments will continue to provide the most powerful range of reagents for our discovery of disease-associated biomarkers and to improve human health through their application as clinical diagnostic and therapeutic reagents. New technologies using antibodies are rapidly increasing, both in scientific and commercial application, stemming from the elucidation of the key elements required for antibody design, efficient expression and desired pharmacokinetics. By providing a highly stable, protease-resistant scaffold, engineered recombinant antibody fragments will continue to be the paradigm for selection of high-affinity clinical reagents for efficient diagnosis and delivery of therapeutic payloads.

Introduction

The lipidome is comprised of all of the biomolecules considered to be lipids, which "... have been loosely defined as biological substances that are generally hydrophobic in nature and in many cases soluble in organic solvents..." (Fahy *et al.*, 2005). This encompasses compounds that are so structurally diverse that they were divided into eight categories by LIPID MAPS, an NIH-funded Consortium that spent a decade exploring ways to facilitate lipidomic studies, and maintains an ongoing website with tools and information. The eight categories were fatty acyls, glycerolipids, glycerophospholipids, sphingolipids, sterol lipids, prenol lipids, saccharolipids, and polyketides (Fahy *et al.*, 2005, 2009).

Lipidomics has been defined as "the full characterization of lipid molecular species and of their biological roles with respect to expression of proteins involved in lipid metabolism and function, including gene regulation" (Spener *et al.*, 2003), but from the earliest days of use of the suffix '-ome' in reports on lipid analysis (Kishimoto *et al.*, 2001; Han and Gross, 2003) to today, it has only been technically feasible for a lipidomic analysis to encompass a fraction of the total lipid species – albeit sometimes large numbers of compounds – but certainly not the entire lipidome. Thus, some of the important questions to answer when examining a report of a lipidomic analysis are 'what was measured?' and 'for what purpose?' and 'was the appropriate method used to provide the desired data?' Some might consider the first question to be 'why lipidomics?' so that will be addressed, too.

Why Lipidomics?

An 'omic' analysis of any type (lipidomics, genomics, etc.) has two types of justifications that sometimes overlap but can

be quite different. One – the 'systems biology' perspective – is to obtain enough information about a biological system to derive equations that describe it and enable predictions about additional features, including future outcomes. This goal can be motivated by scientific curiosity or a desired application, such as to predict how perturbation of one step of a pathway by a drug might impact other metabolites. The other – sometimes called 'discovery science' – is to try to find something unexpected about a biological system that might challenge current hypotheses and/or enable new ones to be proposed. This foray into the realm of 'the unknown unknowns' can also have practical application if, for example, it enables discovery of a disease biomarker or an off-target effect of a drug.

The application of an 'omics' approach to lipids is clearly justified from both of these perspectives because their metabolic pathways are highly interconnected, beginning with a shared biosynthetic precursor and interwoven by downstream intermediates, as illustrated in Figure 1.

This diagram illustrates how acetyl-CoA is a common precursor of all eight lipid categories. After it has been utilized to make the distinguishing compounds in one category (e.g., fatty acids), these will be utilized to produce compounds in other lipid categories, as shown for the acyl-groups of the glycerol(phospho)lipids, the sphingoid base and amide-linked fatty acyls of sphingolipids, and sterol esters, to name just a few of the cases where compounds in one category are metabolically related to other categories.

In addition, the lipidome is comprised of not just compounds that are made *de novo* (colloquially 'from scratch') by an organism (e.g., mammals for the example in the inner box of Figure 1) but also from food and other sources, including gastrointestinal microflora (possible sources of saccharolipids and polyketoides as well as other lipids). When all of these are taken into account, the numbers of distinct molecular

Figure 1 An overview of lipid categories and some of their metabolic interrelationships. This diagram is a modification of a LIPID MAPS summary illustrating how eight lipidome categories are fundamentally related by their precursors (acetyl-CoA and downstream metabolites). It also displays how later metabolites are also shared; for example, fatty acids for biosynthesis of the glycerol(phospho)lipids, sphingolipids, and sterol esters made by mammals (and saccharolipids by other organisms). The mammalian lipidome is also impacted by lipids encountered from food and other routes such as gastrointestinal microflora.

species is mind-boggling: the number of structural variations in lipids has been estimated to be $> 10^5$ (Dennis, 2009), and this is probably an underestimate because novel compounds continue to be found.

Description of How the Components of the Lipidome Are Usually Analyzed

The large number of lipids and the high degree of structural variation among, and even within, the eight categories makes their analysis much more challenging than for most other categories of metabolites. While it has been possible to profile some lipids by common structural features, such as glycolipids that can be captured by lectins that bind the carbohydrate moiety, for a more comprehensive lipidomic analysis it is necessary to use a method that is highly structure specific – and preferably can also be quantitative – such as mass spectrometry (MS).

The power of mass spectrometry is that compounds can be detected in very small amounts once they are ionized, and instruments are available to resolve ions by the mass to charge ratio (m/z), sometimes with high enough mass accuracy to match the data with the molecular formula of the corresponding lipid(s). The analysis might not need such high mass accuracy if the compounds of interest can be distinguished

otherwise (e.g., by their behavior on chromatography prior to mass spectrometry); however, the experimenter must always validate that the ions truly reflect the compound that it has been presumed to be. This is even important when the instrument has a high mass accuracy (such as a time-of-flight, ToF, or fourier transform ion cyclotron resonance, FT-ICR mass spectrometers) because many lipids are isomeric (such as glucosylceramides vs galactosylceramides, which vary only in the stereochemistry of one of the hydroxyls on the carbohydrate) and/or are isobaric (i.e., have the same mass but different composition) within the accuracy of the analysis.

Additional information can be acquired about the compound from other features of the mass spectrum, such as the isotopic distribution, evidence that the compound is present as multiply charged species, etc. In metabolism studies, one can also introduce compounds that are enriched in stable isotopes and track these into downstream metabolites.

Lipidomic analysis requires a myriad of choices that must be made, and these steps will be discussed here and in the following sections of this article. The critical choices are summarized in Figure 2 and additional information can be found in excellent reviews (Murphy and Axelsen, 2011) and monographs on this topic (Brown, 2007). The first depend on the goals of the study: Is quantitation of the lipids necessary? If so, then a targeted LC-MS/MS protocol with multiple extractions and internal standards will probably be required. Is

Figure 2 A flow diagram for the types of technical choices that can be used for a lipidomic analysis. Depending on the sample and the information desired, one might elect to extract the lipids or analyze them *in situ*. If extracted, the compounds can be analyzed using a 'one-size-fits-all' extraction protocol or with multiple extraction schemes that ensure high recoveries for all lipidomic categories (this has been called the CLASS approach for comprehensive lipidomics analysis by separation simplification). The extracts can be analyzed by a 'shotgun' approach, which often involves introducing the entire sample into the mass spectrometer and having it conduct a broad, but high resolution, scan to identify as many compounds as possible, or if comparing two samples, features in the spectra that differ and might be interesting to pursue. In the chromatography toolkit, a variety of methods can be used to partially separate the lipids to minimize ionization suppression of minor species as well as to separate compounds that cannot be distinguished by mass spectrometry alone (such as isomers). In the mass spectrometry toolkit, ion trap (which includes quadrupole and orbitrap), time-of-flight, and FT-ICR can be used alone or in combination with one another. If analysis *in situ* is desired, this can be conducted by methods that ablate ions from the surface of the material directly (such as DESI and SIMS) or by first impregnating the sample with a matrix material that can be excited by a laser to generate ions (MALDI).

the goal to discover potential biomarkers by surveying a large number of samples? If so, then an untargeted approach might be the best choice. Is it important to know the location of the analyte(s) in a sample such as a histological slice? If so, then an imaging MS method is usually selected.

Getting Started – Sample Preparation for Lipidomic Mass Spectrometry

With the exception of imaging MS methods, which generate ions from the surface of a material (SIMS and DESI) or within the sample with imbedded MALDI matrix compounds (for more information, see [Murphy and Merrill, 2011](#)), lipidomic studies begin with extraction of the lipids from the samples to be analyzed. This presents two of the most vexing problems of lipidomic analysis: (1) that lipids across multiple categories vary so widely in both their structures and chemical/biophysical properties; and (2) that lipids differ in amounts by many orders of magnitude. Thus, it is difficult – and perhaps even impossible – to find a single extraction protocol that will efficiently extract compounds that vary so much in: stability – from very chemically stable ceramides to easily oxidized polyunsaturated glycerophospholipids; hydrophobicity – from very hydrophobic triacylglycerols to highly polar gangliosides; and amount – from highly abundant sterols to trace amounts of signaling lipids.

There have been many approaches to lipid extraction, and to some degree, most of the protocols followed today are similar to the 'classic' Bligh and Dyer and Folch extraction methods with modifications to improve the recovery of particular categories of lipids. However, even within a single category of lipids, one protocol might not be able to extract all of the subspecies with high yield; therefore, multiple protocols are used to cover all categories in this type of lipidomic study. This has been referred to as CLASS lipidomics for 'comprehensive lipidomics analysis by separation simplification' ([Harkewicz and Dennis, 2011](#)).

The CLASS protocols of LIPID MAPS were optimized with 'cocktails' of internal standards by the LIPID MAPS Consortium and have been compiled in reviews published in *Methods in Enzymology* ([Brown, 2007](#)) which can be downloaded as a single PDF on the LIPID MAPS website. Some of the procedures were expanded in later reports ([Murphy and Merrill, 2011](#)). The 'LIPID MAPS' internal standards can be obtained from Avanti Polar Lipids (Alabaster, AL) ([Sims et al., 2014](#)) for most of the categories and from Cayman Chemicals (Ann Arbor, MI) for eicosanoids.

There have been a number of recent reports of single extraction protocols that seem to work well with several categories of lipids ([Lydic et al., 2014](#); [Reis et al., 2013](#)), but the number of compounds that have been examined has been

fewer than for the CLASS protocols, so it is not known if single-solvent protocols will become prevalent for broader-based lipidomics analysis. Single extraction protocols have been mainly used in untargeted lipidomic studies where the goal is to survey a wide spectrum of ions to look for noticeable differences between two biological samples (Harkewicz and Dennis, 2011). In this context, the term 'lipidomic' connotes that a wide profile has been examined rather than that all species have been analyzed quantitatively.

Lipidomic Mass Spectrometry

Most lipidomic analyses use some form of chromatography prior to mass spectrometry (as shown in Figure 2), but the mass spectrometric analysis will be discussed first. An excellent source for information about the analysis of each category of lipid by mass spectrometry has recently been published (Murphy, 2015) and is available in print and online.

Mass spectrometry

Mass spectrometry is quite simply the analysis of compounds using an instrument that can separate the ionized state of the compounds by their mass to charge ratio (m/z). Since the exact mass can be calculated for any compound, one can use the m/z to verify that a compound has its presumed molecular composition. *Vice versa*, when presented with a mass spectrum and a spreadsheet with the m/z of the detected ions, one can attempt to deduce the molecular composition of the ions. This might sound simple, but a number of factors complicate structural assignments from the m/z of lipids, such as: (a) for compounds to be seen, they must be ionized under the conditions of the analysis, and this varies considerably for different lipids; (b) even if a compound can be ionized, its behavior might be affected by the presence of other lipids, especially when there are large amounts of other compounds that might promote formation of aggregates; (c) some compounds are chemically unstable under the ionization conditions, so they might not be seen at all at the predicted m/z (this is not always a problem because the decomposition product might suffice as an ion for the compound); (d) depending on the mass accuracy of the instrument, there will probably be several to dozens of compounds that share the same m/z within experimental error; (e) even if the mass accuracy allows an exact molecular composition to be assigned, there are a large number of isomeric and isobaric lipids, which preclude absolute structural identification; and (f) each compound will give more than one m/z because it will also be comprised of high-mass natural abundance isotopes (e.g., ^{13}C), which can also result in the isotopomer of a high-abundance compound to obscure the signal from a lower abundance compound of interest with the same m/z .

Despite these limitations, a high-resolution mass spectroscopic analysis of biological samples without optimizing extraction protocols (such as in a 'shotgun' mode) can be very informative, especially if combined with chromatography or other techniques that help overcome some of these technical limitations (Wang and Han, 2014).

Tandem mass spectrometry

The method that is most often used to confirm the identity of the primary ion is tandem mass spectrometry, where ions of a selected m/z from the first mass analyzer are fragmented by a process termed collision-induced dissociation (CID) and information about the fragments is obtained using another mass analyzer. This is called 'tandem MS,' 'MS/MS,' or 'MS².' Multiple repetitions of this process (n times) is called 'MSⁿ.' Multiple MS analysis is usually conducted with an instrument with 'ion trapping' capability, which allows for the filtration of specific ions and fragments within the mass spectrometer. As described herein, the combination of MSⁿ and ion trap is a powerful technique that can be utilized to robustly measure specific lipids.

Since different categories of lipids typically undergo distinct fragmentations, the precursor-product pairs can distinguish between many of the isobaric compounds, but often does not distinguish isomers. The precursor-product pairs can also be used for a type of analysis termed 'multiple reaction monitoring' (MRM) where the first mass analyzer is set to pass a particular precursor m/z and the second mass analyzer to detect its partner product m/z . By programming the instrument to cycle among a selected set of ion pairs, the instrument can optimize the data collection time for compounds of interest, which is particularly useful when the sample is flowing through the instrument transiently, such as during a chromatographic separation. Some instruments also have the capacity perform more sophisticated operations, such as to have features activated when particular ions are detected (e.g., to scan a full spectrum, or analyze particular product m/z when a particular precursor m/z of interest is detected).

This process is summarized in Figure 3 using ceramides as an example of the main steps that are taken in setting up a protocol for analysis of lipids by liquid chromatography-tandem mass spectrometry (LC-MS/MS). In the first step, lipid standards are examined by MS to determine the types of ions that are detected by the instrument(s) available to the investigator (it is worth mentioning here that due to the high cost of these instruments, the type of analysis is sometimes influenced by the instrument that happens to be available to the investigator). In this figure, C16-ceramide (N-palmitoylsphingosine) has been infused into the mass spectrometer (an ABI 4000 Qtrap) in methanol with electrospray ionization (ESI). Note that the protonated ceramide (abbreviated $[\text{M} + \text{H}^+]$) is not the most abundant ion in this spectrum because there is a large amount of the Na^+ adduct (labeled $[\text{M} + \text{Na}^+]$). The appearance of multiple ions is common in mass spectrometry because salts are present in most biological samples and can arise from glass test tubes and solvents.

The next spectrum in Figure 3 shows the fragments detected when the $[\text{M} + \text{H}^+]$ ion for C16-ceramide (m/z 538.5) is collided with nitrogen (i.e., the process referred to as CID) and the product ions are scanned. Note that there happens to be one major fragment (m/z 264.3) and the structural diagram on the right of the spectrum shows where this fragmentation is thought to occur (i.e., loss of the fatty acyl- and both hydroxyls of the sphingoid base). This fragmentation is common for all chain-length ceramides so one can analyze a mixture of ceramides by varying the precursor m/z and monitoring which

Example of a typical LC-MS/MS analysis protocol

1. Optimize ionization and identify parent ion(s) for analytes of interest (shown here for a C16-ceramide, see structure on the right)

2. Identify major fragmentation product(s) and select candidate precursor/product ion pairs for MRM analysis

Figure 3 An example of a typical protocol for analysis of lipids by liquid chromatography-tandem mass spectrometry (LC-MS/MS). These spectra are for ceramides, but the principles apply to most lipid categories. In the first step, lipid standards are examined by MS to determine the types of ions that are detected by the instrument being used (in this case, electrospray ionization using an ABI 4000 QTrap), then identification of the major product ions upon collision-induced fragmentation of the $[M+H]^+$ precursor ion (see text for further discussion of the spectra, such as the origin of the large Na^+ adduct in the precursor ion spectrum). Having candidate precursor/product ion pair(s) for a MRM analysis (which is a technique to monitor specific precursor/product pairs), the liquid chromatography (LC), ionization and mass spectrometric analysis conditions are optimized. Samples can then be analyzed as they elute from LC (elution of different chain-length subspecies is labeled in red in the third figure). If the relationship between the ion yields for an internal standard (C12-ceramide in this data set) versus the other analytes, then the areas under the curves can be converted to pmol per sample amount.

deliver m/z 264.3 upon CID. Likewise, ceramides with other sphingoid base backbones (different chain lengths, number of double bonds, or hydroxyls) will give different product m/z (266.3, e.g., from dihydrosphingosine, also named sphinganine), so this can be used to monitor those subspecies of compounds. The efficiency of ionization and fragmentation will usually vary for different subspecies, so this must be taken into consideration if one plans to obtain quantitative information about a sample of interest by including adequate internal standards.

Chromatography in combination with mass spectrometry

To separate compounds that cannot be distinguished by fragmentation patterns alone, one often utilizes some form of chromatography to separate the isomers before MS: gas, GC; high performance-liquid, ultra-high performance liquid, UPLC; supercritical lipid, SFC; and others). Additional

advantages of chromatography are that it often removes interfering ions (such as the Na^+), and helps minimize a process termed 'ionization suppression,' wherein the presence of other lipids, salts, or other factors interfere with formation of ions from the compounds of interest.

Having candidate precursor/product ion pair(s) for a MRM analysis (MRM, which is a technique to monitor specific precursor/product pairs), the liquid chromatography (LC), ionization and mass spectrometric analysis conditions are optimized. Samples can then be analyzed as they elute from LC (elution of different chain-length subspecies is labeled in red in the third diagram of Figure 3). If the relationship between the ion yields for an internal standard (C12-ceramide in this data set) versus the other analytes, is known, then the areas under the curves can be converted to pmol per sample amount. This the most common type of mass spectrometry used for CLASS analysis.

'Shotgun' lipidomic mass spectrometry

In addition the techniques described above, there have been other approaches that provide quicker profiling by 'shotgun lipidomics' which sometimes refers to reliance on the mass spectrometer to provide the lipid 'separation' by identification of the species based on their m/z measured with high mass accuracy (Wang *et al.*, 2014). There have been considerable advances in 'shotgun' methodologies by addition of complementary methods for compound identification (including MS/MS scans that are triggered when ions of interest are detected, as well as pre-MS separation by LC, etc.) (Wang and Han, 2014). Another consideration is whether the analysis is targeted (as are most of the CLASS protocols described in the preceding sections) or untargeted, where all ions are collected and distinctions between two states (e.g., healthy versus disease) are determined by statistical analysis of the data sets and identification of the lipids using mass spectral and retention index libraries (Kind *et al.*, 2009).

Ion-mobility mass spectrometry

Another approach to distinguish isomers is the use of ion-mobility spectrometry (IMS) (Kliman *et al.*, 2011), which occurs after, rather than before, the ions are generated, as shown in Figure 2 in the box with dashed lines. In this technique, the ions are passed through a carrier buffer gas that retards compounds based on their collisional cross-section, which often differs for isomers. IMS has been applied, for example, to the localization of fatty acyl and double bond positions

(Castro-Perez *et al.*, 2011), and works well in combination with hydrophilic interaction liquid chromatography and reversed phase chromatography for increased resolution, specificity, and signal-to-noise ratio (Baker *et al.*, 2014).

Selection of instruments for lipidomic mass spectrometry

The box on the far right of Figure 2 illustrates that a wide variety of instruments are used for analysis of lipidomics samples. They differ in their features in many ways, but as a simple comparison, quadrupole and ion trap instruments tend to be workhorses for quantitative analysis of compounds by LC-MS/MS, and time-of-flight (ToF), orbitrap and FT-ICR instruments are slower but employed when greater mass accuracy is needed.

Tissue-imaging mass spectrometry

This analytical approach has been included in Figure 2, but is shown in more detail in Figure 4. Tissue-imaging mass spectrometry can be advantageous because the biological material is not homogenized and extracted (as symbolized by the blender in Figure 4), but rather ions are generated on the surface of the biomaterial – often tissue slices but sometimes intact organisms. The ions are generated by several methods. In secondary ion mass spectrometry (SIMS), the sample is bombarded with a focused primary ion beam and the ejected secondary ions are analyzed. The ion beams are often of such high energy that organic compounds decompose during ionization, but milder methods using a buckminsterfullerene

Figure 4 A diagrammatic representation of the differences between lipidomic analysis for samples that have been homogenized and extracted (upper portion of the diagram) versus analyzed *in situ* by SIMS, DESI, or MALDI Tissue-imaging mass spectrometry. Modified from Murphy, R., Merrill, A.H. (Eds.), 2011. Lipidomics and imaging mass spectrometry. *Biochimica et Biophysica Acta* 1811, 635–1000.

(C_{60}) cluster ion beam is less destructive to the lipids (Wino-grad and Garrison, 2010). In desorption electrospray ionization (DESI), an electrically charged solvent is sprayed onto the sample surface and the charged compounds are analyzed in the ejected droplets (Takats *et al.*, 2005). In the methods that use MALDI to generate ions, the sample is usually deposited on a chilled MALDI plate or a conductive glass slide, the MALDI matrix compound is imbedded in the sample as uniformly as possible with minimal disruption of the lipid localization of the tissue (usually by some type of spraying method), then a laser beam is moved incrementally across the sample (described by the term 'raster') to generate ions for analysis by mass spectrometry (Murphy *et al.*, 2009).

As illustrated for MALDI tissue-imaging MS in Figure 4, once the spectra have been collected, the location of any ion(s) of interest can be visually displayed for images that are much like a microscopic analysis of the sample (e.g., an H&E stain as shown in Figure 4), but with the images representing the distribution of that compound. A caveat for MALDI tissue-imaging MS is that the intensity of the ions can be affected by their local environment and other factors, however, this has nonetheless proven to be a powerful tool for gathering information about the location of lipids and other compounds in tissues.

In general, the region that is undergoing ionization is considerably smaller for SIMS (nanometers to sub-micrometers) than MALDI and DESI (typically, 10 to 100 μm in diameter). All of the procedures generate a huge number of individual spectra, but imaging software is available which allows the ions of interest to be displayed (often with a different

color for each ion displayed) in a manner equivalent to a molecular image.

Lipid Categories of the Lipidome

There are several online resources provide information about lipid structures and nomenclature, tools to facilitate lipid analysis, metabolic pathways and genes, and sometimes updates and notices of upcoming conferences. Of note are the American Oil Chemistry Society (AOCS) Lipid Library, LIPID MAPS, and LipidBank (the web addresses are given at the end of this article). In an attempt to obtain uniformity in nomenclature and the way to display the structures of these compounds, the LIPID MAPS Lipid Classification system (Fahy *et al.*, 2005, 2009) has been adopted by some journals, and the website provides downloadable structure diagrams for many different lipids. The following sections highlight the types of structures that distinguish each lipid category and briefly describe some of the features that are utilized in their analysis. The subsections also mention some of the features that are utilized in lipidomic mass spectrometry, but a full bibliography of those methods are beyond the scope of this article and readers are referred to the already cited monographs and reviews for that information.

Fatty acyls

The fatty acyls are comprised of carbon atoms arranged in chains of varying length, unsaturation, branching, and other features (e.g., presence of hydroxyl-groups, cyclopentene, peroxy, nitro, etc. moieties). Their structures are abbreviated with

Figure 5 Representative features of three major lipid categories: Fatty acyls, glycerolipids, and glycerophospholipids. A general prototype for these compounds is shown in the upper diagram with R1 and R2 representing the alkyl chains of fatty acids attached to the glycerol backbone at these two positions and at position 3 is attached the glycan.

the number of carbon atoms followed by the number of double bonds and any other relevant information, such as the double bond position and whether *cis* (Z) or *trans* (E). Some of the better known members are the saturated fatty acids palmitic acid (C16:0) and stearic acid (C18:0), the mono-unsaturated fatty acid oleic acid (C18:1, 9Z) and poly-unsaturated fatty acids such as linoleic acid (C18:2, 9Z,12Z) and arachidonic acid (C20:4, 5Z,8Z,11Z,14Z), and the broad spectrum of highly bioactive metabolites that fall under the category of eicosanoids (prostaglandins, leukotrienes, etc.). The fatty acyl category also includes compounds such as fatty acyl-CoA's, fatty amides, etc.

Fatty acids have long been analyzed by derivatization and GC-MS, but the negatively charged carboxylate also allows them to be seen by ESI, with assistance in structural identification by using LC-MS/MS (Hellmuth *et al.*, 2012). They are not easily fragmented by CID in structurally informative ways, so many strategies have been developed to gather 'omic' scale information by shotgun lipidomic analysis (Yang *et al.*, 2011) and for quantitation, EI-GC/MS, ESI-LC/MS, and ESI-LC/MS/MS using stable isotope labeling (Murphy and Axelsen, 2011). Quantitation can also be performed without fragmentation using 'pseudo-molecular' MRM, in which the ions do not fragment (Schiesl *et al.*, 2010), but this is limited by

identifying fatty acid species by retention time and the precursor ion. This allows for identification and quantitation of fatty acids by utilizing two MRM transitions (Hellmuth *et al.*, 2012).

Glycerolipids

Glycerolipids typically have a 1,2-diacyl-*sn*-glycerol moiety (as shown in the prototype in Figure 5) where R1 and R2 are long-chain fatty acids in ester linkage to the glycerol backbone. In some cases, a fatty alcohol can be linked to the glycerol backbone by an ether linkage. Since glycerol per se does not have stereochemistry, the 'sn' designation of glycerolipids (standing for 'stereospecific numbering') takes into account that stereoisomers are generated once asymmetric substituents have been added to the hydroxyls. Glycerolipids are found as mono-, di-, and tri-glycerides and with other groups attached, including carbohydrates, which are commonly found in plants, algae, and bacteria (Holzl and Dormann, 2007; Zhang *et al.*, 2014). When phosphorylated, they fit in the next category, glycerophospholipids.

Glycerolipids are commonly measured by mass spectrometry neutral loss scanning wherein the data is collected for precursor and product ions that differ by the unit of what has been lost (in this case, due to fragmentation at the ester

Figure 6 Representative features of three major lipid categories: sphingolipids, sterols, and prenyls. Sphingolipids are comprised of a sphingoid base (shown for sphingosine) that can be derivatized with an amide-linked fatty acid (for ceramide) and/or addition of a headgroup at the hydroxyl on carbon 1, with the simplest cases being sphingosine-1-phosphate and ceramide-1-phosphate (Cer1P). SM and CPE refer to sphingomyelins and ceramide phosphoethanolamines which have the phosphocholine and phosphoethanolamine headgroups, respectively. The glycan headgroups include simple monosaccharides (glucose or galactose) to very complex polysaccharides (such as those found in gangliosides). Sterols have variations of the 4-ring system shown for cholesterol as well as additional groups such as addition of a fatty acid or carbohydrate to the free hydroxyl at carbon 3. Prenols are comprised of isoprene units (shown in brackets) on some combination (the compounds shown are linear polymers, but they can also be part of rings, as in the case of retinol, ubiquinone, etc.). The dolichols and bactotrenols that are shown can be linked to glycans via phosphate or pyrophosphate diesters.

bonds) (Murphy, 2015). Na^+ is often added to facilitate detection of the positively charged adducts (Callender *et al.*, 2007; Murphy and Axelsen, 2011; Murphy *et al.*, 2011).

Glycerophospholipids

The glycerophospholipids have a so-called 'phosphatidic acid' backbone (i.e., 1,2-diacylglycerol 3-phosphate) as shown in Figure 5. If a headgroup is added in phosphodiester linkage, the compound is named phosphatidyl-'headgroup' (such as phosphatidylcholine, PC) unless one of the alkyl chains is a fatty alcohol attached in ether linkage, in which case it is commonly referred to as an alkyl ether- or alkenyl ether-phospholipid (the term 'phosphatidal' is often used when the ether linkage is with an O-alkenyl group). Some organisms, such as Archaea, have two isoprenoid chains attached to positions 2,3 of glycerol via ether bonds as their way of forming an ether lipid (in this case, 2,3-diphytanyl-*sn*-glycerol) (Mori *et al.*, 2014). If there is only one fatty acyl or ether-linked alkyl chain, the name is usually preceded with 'lyso.'

The most common headgroups for glycerophospholipids are choline (PC), ethanolamine (PE), serine (PS), inositol (and its phosphates) (PI, PIP, PIP₂, etc.), and glycerol (PG), which is also present in cardiolipid, 1,3-bis(phosphatidyl)-glycerol (Figure 5). There are also other glycerophospholipid linked glycans, such as CDP-diacylglycerol, a biosynthetic intermediate for phospholipid biosynthesis by many organisms, phosphatidylglucose (Ishibashi *et al.*, 2013), and the 'glycosylphosphatidylinositol anchor' (GPI) that is used to attach some categories of proteins to membranes (Paulick and Bertozzi, 2008).

Glycerophospholipids are often analyzed by loss of the headgroup since the phosphate bond is relatively labile during CID, which gives a backbone atomic composition (i.e., total number of carbons, oxygens, and double bonds) but not the specific fatty acyls and their position (Brown, 2007; Murphy, 2015). Therefore, these data are reported for the sum of the alkyl chain carbons instead of specific molecular species. There are also methods that produce fragments that give information about specific fatty acyls and position (Maccarone *et al.*, 2014).

Sphingolipids

Sphingolipids are defined by containing sphingosine (Figure 6) or another sphingoid base as part of their structure. There are many variations in this backbone lipid moiety, especially for microorganisms and invertebrates (Pruett *et al.*, 2008). For most sphingolipids (i.e., the so-called 'complex' sphingolipids), the amino group is connected to a fatty acid, and these compounds are generically referred to as 'ceramides.' There are also hundreds of different headgroups attached to the hydroxyl-group on the first carbon, which fall in the subcategories of phosphosphingolipids (sphingomyelins, ceramide phosphoethanolamines, ceramide-1-phosphates, and others), neutral glycosphingolipids (where the headgroup is comprised of uncharged sugars – glucose, galactose, glucosamine, galactosamine, and fucose, for mammals), and acidic glycosphingolipids, such as gangliosides (which have sialic acid) and sulfatides (sulfated glycans) and others (for overviews, see Yu *et al.*, 2007; Merrill, 2011 and the 'sphingomap' web site).

Lipidomic methods are available for analysis and quantitation of the sphingolipids that comprise the major components of most of mammalian plasma and cells, which include most of the compounds implicated in cell signaling (sphingosine-1-phosphate, ceramides, ceramide-1-phosphate, etc.) (e.g., see Shaner *et al.*, 2009). The more complex (and often less abundant) glycosphingolipids pose a bigger analytical challenge. The glycan headgroups are sometimes determined after removal of the ceramide (Parry *et al.*, 2007), or for the intact glycosphingolipids, using MSⁿ to identify both the carbohydrates and ceramide backbones (capitalizing on the characteristic fragmentation for ceramides that was illustrated in Figure 3) (Sullards *et al.*, 2011). For examples of these methods, see Farwanah and Kolter (2012) for a general overview of the lipidomics of glycosphingolipids; Ito *et al.* (2012) for a description of the use of atmospheric pressure matrix-assisted laser desorption/ionization (AP-MALDI) coupled to a quadrupole ion trap time-of-flight (QIT-TOF) mass spectrometer for soft ionization and MSⁿ analysis of gangliosides; and Kouzel *et al.* (2014) for an example of how glycosphingolipids have been analyzed in crude lipid extracts by treatment with phospholipase C before TLC to separate and prepare the samples for identification using immunostaining and infrared matrix-assisted laser desorption/ionization orthogonal time-of-flight mass spectrometry (IR-MALDI-o-TOF MS) in combination with CID).

Sterol lipids

The most often thought of sterol is cholesterol (Figure 6), its derivatives (sterol esters and steryl glycosides), and metabolites (bile acids, steroid hormones, corticosteroids, and others). However, there are many additional structural variants (sitosterol, ergosterol, campesterol, stigmasterol, brassicasterol, and others) that are produced by plants, fungi, and other organisms. There are probably more subspecies yet to be discovered considering that the presence of cholesterol glucoside in mammalian cells has only been recently appreciated (Ishibashi *et al.*, 2013).

Many sterols are very nonpolar and relatively difficult to ionize without derivatization (Griffiths *et al.*, 2006), and structural similarities often make them difficult to separate for analysis of isobaric and isomeric species. An additional challenge for mammalian systems is that cholesterol is present in such large amounts compared to the bioactive metabolites that the range in amounts is at least six orders of magnitude – from mg ml⁻¹ for cholesterol to ng ml⁻¹ for some trace oxysterols – but with the appropriate care, these barriers have been overcome (McDonald *et al.*, 2012). Indeed, considerable advances have been made in recent years in the separation and analysis of large families of sterols and sterol esters in an 'omic' context by taking advantage of LC and GC chromatography (John *et al.*, 2014; Matysik *et al.*, 2012; McDonald *et al.*, 2012; Murphy *et al.*, 2011).

Prenol lipids

Prenol lipids are synthesized from five-carbon isoprene units (illustrated in the bracket shown in Figure 6) that can be combined in a wide variety of polymeric units and myriad of configurations to make an amazing number of natural products, including fat-soluble vitamins (Thulasiram *et al.*, 2007).

Figure 7 Representative features of two major lipid categories: saccharolipids and polyketides. A general prototype for saccharolipids (acylated glycans) is shown at the top, with an example of the Kdo₂-Lipid A portion of the lipopolysaccharide of gram-negative bacteria (Kdo is the abbreviation for 3-deoxy-D-manno-oct-2-ulosonic acid). The lower portion of the figures shows a polyketide, erythromycin, but this category of compounds is too varied in structure to be represented by a general prototype.

When there are over four isoprene units, they are usually referred to as polyprenols (Vranova et al., 2012), and subdivided into the isoprenoids and quinones/hydroquinones (such as the ubiquinones that are important in mitochondrial electron transport).

Some of the prenyls (i.e., dolichols for eukaryotes and bactoprenol for bacteria) are used in sugar transport across membranes and transfer of carbohydrates to acceptors, with attachment of the carbohydrate to the hydroxyl on the terminal isoprene via a phosphodiester for simple monohexoses and a pyrophosphate for larger oligosaccharides, such as those that are used for N-linked glycoprotein biosynthesis (Welti, 2013). As indicated in the example in Figure 6, the number of isoprene units varies from 18 to 22 for dolichols and 10 to 12 for bactoprenols, and there are also differences in the degree of unsaturation among different sources. The structural variations are becoming more evident as mass spectrometric methods are facilitating the analysis of these compounds (Garrett et al., 2007; Guan and Eichler, 2011).

Saccharolipids

These are compounds in which fatty acids are linked directly to a sugar backbone, as shown in Figure 7 by the general ester bond and example compound. One of the most widely known saccharolipids is Kdo₂-lipid A (Figure 7), which is a component of lipopolysaccharides (LPS) that are present in the outer membranes of most gram-negative bacteria (Raetz et al., 2009). Saccharolipids considerable structural variation among organisms (Banoub et al., 2010), including differences in the

carbohydrates as well as lipids, as represented by the acylated trehalose of *Mycobacteria* (Rombouts et al., 2011). Saccharolipids are often analyzed by a combination of methods to identify both the lipid moieties and glycans (Henderson et al., 2013) since both can exist in many isomeric forms.

Polyketides

These are a structurally diverse group of natural products that are biosynthetically derived from acetyl- or malonyl- units and their structural features (including polyphenols, macrolides, polyenes, enediynes, and polyethers) meet the criterion of being a 'lipid' because most are relatively soluble in organic solvents (Hertweck, 2009). No structural scheme can encompass all of the members of this subclass, so an example, erythromycin, is shown in Figure 7. Other polyketides also have antimicrobial, antiparasitic, and anticancer uses, but some are also toxic, such as the aflatoxin-family carcinogens. Methods for analysis of these compounds are usually focused structural variants and metabolites of each type (e.g., aflatoxins B₁, B₂, M₁, etc.) rather than attempting to encompass all polyketides.

Lipidomics Databases and Other Online Tools

In parallel with the growth of analytical methods for lipidomics, there has been an explosion of lipidomics data and tools in press and online. Besides searching the recent literature to keep abreast of this topic and how it fits into systems biology (e.g., Hyotylainen and Oresic, 2014), one can rapidly

access a large number of tools by examining the LIPID MAPS web site, where there are LIPID MAPS bioinformatics tools and data (as have also been explained in several published reports (Fahy *et al.*, 2007b, 2011)), links to tutorials on how to use the tools and databases, and discussion of their utilization to develop a systems biology of lipids (Subramaniam *et al.*, 2011).

The tools on this website meet the need for high-quality bioinformatics to manage and integrate experimental data at multiple levels (Fahy *et al.*, 2007a): (1) definition of lipid classification and ontologies; (2) relational database design; (3) capture and automated pipelining of experimental data; (4) efficient management of metadata; (5) development of lipid-centric search tools; (6) analysis and visual display of results; and (7) integration of the lipid knowledge base into biochemical pathways and interactive maps. The databases can be queried by text, mass, formula, classification, and other criteria, or most simply by 'Quick search' to obtain information not only about lipids but also MS standards, the lipid proteome database, and pathways. In addition to developing these databases from known compounds, LIPID MAPS has developed a software package called LipidMapsTools for the template-based combinatorial enumeration of virtual compound libraries for lipids (Sud *et al.*, 2012).

Examples of Findings Using Lipidomics Approaches

There have now been such a large number of studies using these types of lipidomics approaches that one should be able to locate publications in their particular area of interest quite easily using online search engines. Therefore, only a few examples will be given here.

CLASS-Type Lipidomic Analysis

The lipidomics studies of the LIPID MAPS Consortium are examples of CLASS-type analyses. Studies using this approach:

- Elucidated changes in the macrophage lipidome upon activation of the cells by Kdo₂-Lipid A (Dennis *et al.*, 2010). These included immediate responses in fatty acid metabolism (increases in eicosanoid synthesis), delayed responses in sphingolipid and sterol biosynthesis, and lipid remodeling for glycerolipids, glycerophospholipids, and prenols. These studies also resulted in numerous 'spin-off' discoveries, including the role of *de novo* sphingolipid biosynthesis in induction of autophagy in these cells (Sims *et al.*, 2010), and the production of 25-hydroxycholesterol and its role in immunomodulation (Shibata *et al.*, 2013).
- Quantified over 500 different molecular species of lipids in six main categories (fatty acyls, glycerolipids, glycerophospholipids, sphingolipids, sterols, and prenols) in human plasma, including detection of 100 subspecies of sphingomyelins (Quehenberger *et al.*, 2010).
- Identified a panel of 20 plasma metabolites that included glycerophospholipids, sphingolipids, and sterols as well as aqueous small molecular weight components that could differentiate between NASH and steatosis in a double-blinded study (Gorden *et al.*, 2015) of samples from individuals with different stages of nonalcoholic fatty liver

disease (NAFLD), which includes steatosis, nonalcoholic steatohepatitis (NASH), and cirrhosis). The lipids included compounds with the novel 1-deoxy-sphingoid base backbone, which have been associated with diabetes.

Shotgun Lipidomics

Use of shotgun lipidomics is illustrated by these studies:

- A targeted shotgun lipidomics analysis of lipid extracts from postmortem brains of subjects with preclinical Alzheimer's disease (i.e., persons who were cognitively normal at death, but displayed neuropathology), found sulfatide levels were significantly lower and ethanolamine glycerophospholipids were marginally lower in subjects with preclinical Alzheimer's disease compared to those without neuropathology (Cheng *et al.*, 2013).
- A study of lipids extracted from 685 plasma samples found that of the levels of individual species of cholesterol esters, lysophosphatidylcholines, phosphatidylcholines, phosphatidylethanolamines, sphingomyelins, and triacylglycerols were associated with cardiovascular disease over a 10-year observation period (Stegemann *et al.*, 2014).

Tissue-Imaging Mass Spectrometry

Tissue-imaging mass spectrometry has been used to:

- Determine the ability of DESI mass spectrometry to identify and differentiate breast tumors from normal breast tissue (Calligaris *et al.*, 2014), which found that several fatty acids (including oleic acid) were more abundant in the cancerous tissue than in normal tissues.
- Profile lipids and proteins in clear cell renal cell carcinoma using MALDI imaging mass spectrometry (Jones *et al.*, 2014), which found a refined panel of 26 proteins and 39 lipid species that could either distinguish tumor from nontumor tissues, or tissues from recurrent disease progressors from nonrecurrent disease individuals.
- Examine coronal sections in a mouse model of chronic alcohol exposure using matrix-implanted laser-desorption/ionization mass spectrometry imaging (MILDI-MSI) which involves implanting silver nanoparticulate matrices followed by focused laser desorption (Roux *et al.*, 2014). This found qualitative regional changes in ion intensities for ceramide and sphingomyelin pairs as a function of group and brain region, in cortex, striatum, accumbens, habenula, and hippocampus, and highly correlated changes in certain white matter regions.
- Establish the spatial organization of lipids in the human retina and optic nerve by MALDI imaging mass spectrometry (Zemski Berry *et al.*, 2014), which found that triacylglycerols were highly localized in accessory tissue, whereas sulfatide and plasmalogen glycerophosphoethanolamines with a monounsaturated fatty acid were enriched in the optic nerve. Several lipids were associated solely with the inner retina, photoreceptors, or retinal pigment epithelium.

Summary

Great strides have been made in lipidomics analysis over the past decade. While only a fraction of the entire lipidome can currently be quantified (somewhat) easily, development of more sophisticated mass spectrometers continues at a break-neck pace and investigators are as quickly applying them to lipids. It will still be challenging to interpret the large amounts of information this technology provides, but that is the inevitable price – pleasant prospect – of having lipids join the ‘omics’ fields.

Glossary

Archaea The kingdom of life composed of single cell microbes lacking a nucleus and internal membrane-enclosed organelles. Although classified as prokaryotes, they are distinct from bacteria in that they contain unique membrane lipids and metabolic pathways of both bacteria and eukaryotes. Many are extremophiles living in harsh environments.

Chirality A system displays chirality if it cannot be superimposed on the mirror image of itself such as the human hand.

Eubacteria The kingdom of life composed of true bacteria as opposed to Archaea. They are single cell microbes lacking a nucleus and internal membrane-enclosed organelles, which distinguishes them from eukaryotes.

Eukaryote The kingdom of life composed of single or multiple cells containing membrane-enclosed organelles including a membrane-enclosed nucleus with defined chromosomes.

Gram-negative bacteria This subgroup of bacteria does not stain with a reagent developed by Hans Gram specific for the cell wall of most bacteria. In Gram-negative bacteria the cell wall, which is exterior to the inner cytoplasmic membrane, is protected by a second outer membrane structure.

Gram-positive bacteria This subgroup of bacteria does stain with a reagent developed by Hans Gram specific for the cell wall of most bacteria. Gram-positive bacteria lack the second outer membrane structure of Gram-negative bacteria thus have an exposed cell wall.

Introduction

Glycerolipid formally refers to molecules with glycerol esterified with long-chain fatty acids at anyone or all of the hydroxyl groups (Figure 1). Triacylglycerol is the storage form of lipids in adipose tissue. Diacylglycerol in trace amounts acts as a metabolic signaling molecule at several locations within cells (Almena and Mérida, 2011). Diacylglycerols with a mono-, di-, or trisaccharide in glycosidic linkage to the free hydroxyl form a group of glycolipids found in eubacteria and plants.

Glycerophospholipids (hereafter referred to as phospholipids) contain fatty acids at the central and one of the distal hydroxyls of glycerol with the remaining hydroxyl in ester linkage to either phosphate or a phosphate in phosphoester linkage to a variety of alcohols as denoted by the X. The

chirality of the glycerophosphate backbone of phospholipids in all forms of life except Archaea is the same with the simplest phospholipid (phosphatidic acid) formally named 1,2 diacyl-*sn*-glycerol-3-phosphate. All glycerolipids in Archaea contain the mirror image configuration of *sn*-glycerol-1-phosphate with long-chain hydrocarbons at the *sn*-2 and *sn*-3 positions. In Archaea the hydrocarbons are made up of 20–40 branched-chain isoprenoid (phytanyl) units, which are in ether rather than ester linkage to the glycerol backbone. This article will cover only phospholipids found in eubacteria, the yeast *Saccharomyces cerevisiae* and mammalian cells. In these organisms the hydrocarbon components of lipids are generally long-chain fatty acids in ester linkage except for the ether lipid subclass of phospholipids (McIntyre *et al.*, 2008) synthesized in mammalian peroxisomes. The hydrocarbons of fatty acids

Figure 1 Basic structure of various glycerolipids. The glycerol carbon backbone (red) is depicted as the conformational isomer found in eubacteria and eukaryotes. R1 and R2 indicate long-chain hydrocarbons, which vary in length, number of double bonds, and degree of branching. The various classes of phospholipid vary in the alcohol in phosphoester linkage at X in the middle diagram. The saccharide (green) is generally glucose (as shown) or galactose and can be up to three units in length.

in extensively studied Gram-negative bacteria, yeast, and mammalian cells are not branched and contain single or multiple unsaturated bonds in over half the chains. In extensively studied Gram-positive bacterial the hydrocarbons chains are usually fully saturated but are branched in nature. Plants and mammalian cells use similar pathways for the synthesis of phospholipids common to both species. Plants contain additional glycerolipids not found in other forms of life.

Synthesis of Phosphatidic Acid

Synthesis of all glycerolipids except the plasmalogens begins with the *sn*-glycerol-3-phosphate derived from direct phosphorylation of glycerol with ATP or the reduction of dihydroxyacetone phosphate. In plasmalogen biosynthesis the free hydroxyl (*sn*-1 position) of dihydroxyacetone phosphate is first acylated with a long-chain fatty acid followed by an exchange reaction where the fatty acid is replaced by a long-chain fatty alcohol resulting in an ether linkage (McIntyre *et al.*, 2008). The ketone at the *sn*-2 position is then reduced to an alcohol and acylated. Although there are differences in the fatty acid donors among organisms, the basic pathway is conserved (Figure 2). Fatty acid synthesis in all organisms proceeds via sequential addition of acetyl Coenzyme A (CoA) units to an acyl chain covalently attached to acyl carrier protein (ACP). In eukaryotic cells ACP is a tightly associated component of the fatty acid synthase complex so that transfer to CoA releases the completed fatty acyl chain. In eukaryotes acyl-CoA derivatives are the source of fatty acid for phosphatidic acid biosynthesis. In eubacteria *de novo* fatty acid synthesis ends with the carboxyl moiety in thioester bond to free ACP, which is not part of a larger synthase complex.

The most common initial acylation step in eubacteria proceeds by first conversion of the fatty acyl-ACP to an acyl phosphate followed by transfer of the acyl group to the *sn*-1 position of glycerol to form lysophosphatidic acid (Yao and Rock, 2013); the *plsX* and *plsY* gene products, respectively, catalyze these two steps. Virtually all of the genes referred to in this article have been mapped, cloned, and sequenced. *Escherichia coli* and closely related Gram-negative bacteria are an exception in that in addition to the above gene products they contain the *plsB* gene product (Larson *et al.*, 1980), which directly utilizes either CoA or ACP derivatives of fatty acids as donors in the first step. The *plsC* gene product catalyzes the second acylation step using ACP linked fatty acids in all bacteria with only *E. coli* and related bacteria also utilizing CoA fatty acid derivatives (Coleman, 1992). All of the enzymes of these pathways are integral to the cytoplasmic membrane of bacteria.

The same basic pathway is utilized by yeast, such as *S. cerevisiae* (Henry *et al.*, 2012), and mammalian cells (Vance and Vance, 2008) to synthesis phosphatidic acid in the endoplasmic reticulum and outer mitochondrial membranes (Figure 2). All acylation steps in eukaryotic cells utilize acyl-CoA derivations since such cells do not contain free ACP. As is generally the case in eukaryotic cells, there is redundancy in the numbers of genes products in each cell, the significance of which has not been fully clarified. In mammalian cells the *GPAT1* and 2 gene products localized to the outer mitochondrial membrane and the *GPAT3* and 4 gene products in the endoplasmic reticulum membrane acylate the *sn*-1 position. The second acylation step is carried out by any of five gene products (*AGPAT1-5*) in the endoplasmic reticulum. In yeast gene products localized to the endoplasmic reticulum catalyze the first (*SCT1* or *GPT2*) and second (*SLC1* or *ALE2*) acylation step.

Figure 2 Biosynthetic pathway for phosphatidic acid and triacylglycerol. Synthesis begins in the lower left corner and utilizes either coenzyme A (CoA), phosphate (P_i) or ACP derivatives of long-chain fatty acids as discussed in the text. Formation of triacylglycerol in eukaryotes involves first remove of phosphate followed by acylation at the *sn*-3 position.

In all organisms phosphatidic acid can be synthesized from diacylglycerol by phosphorylation utilizing ATP. There are multiple processes that generate diacylglycerol within all bacteria and specific organelles within eukaryotic cells. Particularly in the eukaryotic cells where diacylglycerol is a metabolic signaling molecule, mechanisms are required for its rapid generation and removal. Phosphatidic acid is also an important metabolic signaling molecule in eukaryotic cells (Cai *et al.*, 2009). The interconversion of diacylglycerol and phosphatidic acid has important regulatory consequences.

Synthesis of Phospholipids in Bacteria

There are many similarities between eubacterial and eukaryotic pathways of phospholipid biosynthesis and many of the enzymes show high degrees of sequence homology. However, as expected there are many differences. Although Archaea will not be covered in any detail, the pathways resulting in different alcohols at the 'X' position of phosphatidic acid are similar between eubacteria and Archaea (Boucher, 2007).

Synthesis of Amine-Containing Phospholipids

The phospholipids containing an amino group are phosphatidylethanolamine, phosphatidylcholine, and phosphatidylserine where the X position of phosphatidic acid shown in Figure 1 is replaced by ethanolamine, choline, or serine, respectively. The greatest diversity in pathways between bacteria and eukaryotic cells is seen in the synthesis of these phospholipids.

Although the pathways are essentially the same in all bacteria, the best studied are those in the Gram-negative bacterium *E. coli* initially by Eugene P. Kennedy's laboratory in the 1960s. In the following years all of the genes responsible for this pathway were identified, cloned, and sequenced and most of the gene products have been purified and extensively studied (Figure 3). The pathway begins with the synthesis of the common precursor, CDP-diacylglycerol, to all of the major phospholipids found in bacteria (Carter, 1968; Sparrow and Raetz, 1985). The formation of the high-energy pyrophosphate bond in the reaction of phosphatidic acid with CTP provides the energy and driving force to assure that the equilibrium lies in the direction of synthesis of the final products. Displacement of CMP by serine results in conversion of a pyrophosphate bond to a lower energy phosphoester bond with the equilibrium lying far to the formation of phosphatidylserine (Kanfer and Kennedy, 1962; Raetz, 1975, 1976; Larson and Dowhan, 1976). Final decarboxylation of phosphatidylserine to form phosphatidylethanolamine with the release of CO₂ again assures completion of the reaction (Dowhan *et al.*, 1974; Hawrot and Kennedy, 1976; Li and Dowhan, 1988, 1990). Phosphatidylethanolamine ranges from 70 to 80% of the total phospholipid of *E. coli*; virtually all of the phospholipids are found as components of the membrane lipid bilayer with no significant amounts found in the cytoplasm. The precursors to phosphatidylethanolamine are found in amounts of 1% or less.

All the enzymes of phospholipid synthesis in *E. coli*, except the phosphatidylserine synthase, are integral membrane

proteins of the inner cytoplasmic membrane. They are only released from the membrane by disruption of the lipid bilayer by detergents. On the other hand, phosphatidylserine synthase is loosely associated as a peripheral membrane protein easily displaced by high-ionic strength buffers (Louie and Dowhan, 1980). In Gram-positive bacteria, the phosphatidylserine synthase is an integral membrane protein and displays no sequence homology to the *E. coli* enzyme (Matsumoto, 1997).

E. coli and closely related bacteria do not contain phosphatidylcholine, which is present in high amounts in all eukaryotic cells. However, more distant Gram-negative bacteria (Sohlenkamp *et al.*, 2003) contain phosphatidylcholine. One mode of synthesis is by trimethylation of phosphatidylethanolamine by processes similar to that observed in eukaryotic cells (see Figure 6). A second mode is displacement of CMP from CDP-diacylglycerol by choline catalyzed by the *pcs* gene product via a unique bacterial pathway resulting in the formation of phosphatidylcholine (see Figure 4). Both pathways are energetically favorable resulting in high levels of phosphatidylcholine in these bacteria.

Synthesis of Non-Amine-Containing Phospholipids

Beginning with CDP-diacylglycerol, phosphatidylglycerol is formed in two steps by first displacement of CMP by *sn*-glycerol-3-phosphate to form phosphatidylglycerophosphate followed by dephosphorylation of this product to form phosphatidylglycerol (Chang and Kennedy, 1967a,b). Again the equilibrium lies far from completion for these two reactions. It should also be noted that the unacylated glycerol-3-phosphate is the *sn*-1 isomer in contrast to the lipid backbone *sn*-glycerol-3-phosphate. There are three genes, *pgpABC* (Icho and Raetz, 1983; Funk *et al.*, 1992; Lu *et al.*, 2011), that encode phosphatases but only one gene, *pgsA* (Hirabayashi *et al.*, 1976; Ohta *et al.*, 1981) that encodes the synthase. The phosphatases reside in different cellular compartments such as the inner and outer membranes of *E. coli* and their active sites may be facing different sides of their respective membranes. These phosphatases also act on other lipid phosphates. The *pgpC* gene product appears to be the major biosynthetic enzyme. These phosphatases have numerous homologs in other bacteria. The *pgsA* gene product is highly homologous across the bacterial kingdom, but shows no homology to its eukaryotic counterpart.

The final step in this pathway is the formation of the unique phospholipid cardiolipin by the condensation of two phosphatidylglycerol molecules with the release of glycerol (Hirschberg and Kennedy, 1972; Pluschke *et al.*, 1978; Ohta *et al.*, 1985; Hiraoka *et al.*, 1991; Guo and Tropp, 2000; Tan *et al.*, 2012). Since the reaction involves an interchange among phosphodiester bonds of near equal energy, this reaction is reversible. The result is that phosphatidylglycerol comprises about 20% and cardiolipin about 5–10% of the total phospholipid. In fact in stationary phase where little new net synthesis of phospholipids occurs, cardiolipin becomes the predominate lipid of this branch of the pathway. Again there are multiple genes encoding cardiolipin synthases in all bacteria. Of the three *clsABC* gene products, *clsA* appears to be the primary biosynthetic enzyme and catalyzes the condensation

Figure 3 Biosynthetic pathway for phospholipids in *E. coli*. Each step of the pathway is catalyzed by the following enzyme encoded by the genes indicated next to each number: (1) CDP-diacylglycerol synthase; (2) phosphatidylserine synthase; (3) phosphatidylserine decarboxylase; (4) phosphatidylglycerophosphate synthase; (5) phosphatidylglycerophosphate phosphatases; and (6) cardiolipin synthases. The phosphatidyl donor for the *clsB* gene product has not been fully characterized but may also be phosphatidylethanolamine. Reprinted from Dowhan, W., 2013. A retrospective: Use of *Escherichia coli* as a vehicle to study phospholipid synthesis and function. *Biochimica et Biophysica Acta* 1831, 471–494, with permission from Elsevier B.V.

Figure 4 Synthesis of foreign lipids in *E. coli*. The pathways found in *E. coli* are noted by blue arrows. The following enzymes with their respective genes named and source indicated carry out (red arrows) the following steps: (1) phosphatidylcholine synthase (*Legionella pneumophila*) (Conover *et al.*, 2008); (2) phosphatidylinositol synthase (*S. cerevisiae*) (Xia and Dowhan, 1995); (3) monoglucosyl diacylglycerol synthase (*A. laidlawii*) (Xie *et al.*, 2006); (4) diglucosyl diacylglycerol synthase (*A. laidlawii*) (Wikstrom *et al.*, 2009); and (5) lysyl t-RNA: phosphatidylglycerol lysine transferase (*S. aureus*) (Oku *et al.*, 2004). Adapted from Dowhan, W., 2013. A retrospective: Use of *Escherichia coli* as a vehicle to study phospholipid synthesis and function. *Biochimica et Biophysica Acta* 1831, 471–494 and reprinted with permission from Elsevier B.V.

of two molecules of phosphatidylglycerol (Hirschberg and Kennedy, 1972). The other two enzymes form cardiolipin by condensation of phosphatidylglycerol with phosphatidylethanolamine with the release of ethanolamine (Tan *et al.*, 2012). While *clsA* is expressed under all growth conditions, the other two genes are not. The significance of this multiplicity of enzymatic activities is not yet understood.

Gram-positive bacteria and bacteria lacking a cell wall such as *Acholeplasma laidlawii* contain the completely neutral glycolipids with mono-, di-, or trisaccharides at the *sn*-3 position of glycerol (see Figure 1). These are made by successive transglycosylation reactions first to diacylglycerol followed by extension of the number of sugars with UDP-sugars as the donors (Dahlqvist *et al.*, 1992). These glycerolipids comprise 20–40% of the membrane lipids of these organisms. Not positively charged phospholipids are also found in many Gram-positive bacteria such as *Staphylococcus aureus* (Oku *et al.*, 2004). These are formed by the addition of an amino acid to the free hydroxyls of phosphatidylglycerol using an amino acid charged t-RNA as a donor (see Figure 4).

Viable strains of *E. coli* have been made completely devoid of gene products at each step of phospholipid synthesis after the synthesis of CDP-diacylglycerol (Dowhan, 2009). These mutants still form efficient membrane bilayers that maintain cell integrity but lack specific phospholipids. Each displays a set of phenotypes that have been correlated with a requirement for the missing lipids. These mutants have been used to implicate specific lipids in electron transport and energy production, protein translocation across and insertion into

membranes, the topological organization of membrane protein transmembrane domains, initiation of DNA replication, cell division, chemotaxis, and formation of lipid domains in cell membranes. Domains enriched in specific phospholipids appear to be sites for organization of molecular machines involved in DNA replication and cell division (Mileyskovskaya and Dowhan, 2005). In addition foreign lipids have been synthesized in *E. coli* by introduction of genes responsible for synthesis of these lipids in other organisms (Dowhan and Bogdanov, 2012). Figure 4 summarizes the lipids that have been introduced into *E. coli*. Such strains have assisted in understanding the properties of lipids that support various cell processes defective in lipid mutants of *E. coli*.

Synthesis of Phospholipids in Eukaryotes

Phospholipid synthesis in mammalian cells (Vance and Vance, 2008) and the yeast *S. cerevisiae* (Henry *et al.*, 2012) have been extensively detailed both biochemically and genetically.

Synthesis of Amine-Containing Phospholipids

The synthesis of amine-containing phospholipids in mammalian cells is vastly different from that observed in bacteria. However, yeast possess pathways of both mammalian cells and bacteria. Yeast synthesis of phosphatidylserine and phosphatidylethanolamine occurs via the bacterial pathway

(Figure 3) by a membrane-associated enzyme (*CHO1/PSS1* gene product) in the endoplasmic reticulum followed by transfer to the inner mitochondrial membrane (*PSD1* product) and to Golgi/vacuole membranes (*PSD2* gene product) for decarboxylation to phosphatidylethanolamine (Clancey *et al.*, 1993; Trotter *et al.*, 1993; Voelker, 1997). The two decarboxylases show limited homology, but the mitochondrial-localized *PSD1* gene product shows significant homology with the *E. coli* enzyme. How phosphatidylserine and phosphatidylethanolamine traffic between the mitochondria and the

endoplasmic reticulum is an area of active investigation (Osman *et al.*, 2011).

The pathway for the synthesis of these phospholipids found in all eukaryotic cells is referred to as the Kennedy Pathway (Kennedy, 1956; Kennedy *et al.*, 1956, 1959; Kennedy and Weiss, 1956; Borkenhagen and Kennedy, 1957; Smith *et al.*, 1957; Weiss *et al.*, 1958) in recognition of its founder (Figure 5). The pathway is localized initially to the cytoplasm for the formation of water-soluble precursors and then to the endoplasmic reticulum membrane for the synthesis of the final

Figure 5 Biosynthetic pathway for amine-containing phospholipids in eukaryotes. The genes encoding the enzymes responsible for each step are noted next to the numbers. Gene names in red are the same for yeast and mammalian cells. Genes in blue or green denote a yeast or mammalian cell gene, respectively. (1) choline kinase; (2) CTP: phosphocholine cytidyltransferase; (3) ethanolamine kinase; (4) CTP: phosphoethanolamine cytidyltransferase; (5) phosphatidic acid phosphatase; (6) CDP-choline:1,2-*sn*-diacylglycerol cholinephosphotransferase; and (7) CDP-ethanolamine:1,2-*sn*-diacylglycerol ethanolaminephosphotransferase. Adapted from Dowhan, W., 2013. A retrospective: Use of *Escherichia coli* as a vehicle to study phospholipid synthesis and function. *Biochimica et Biophysica Acta* 1831, 471–494 and reprinted with permission from Elsevier B.V.

lipid products. How phospholipids are transported from their site of synthesis in the endoplasmic reticulum to the membranes of other organelles is not completely understood. The choline and ethanolamine precursors are first phosphorylated by ATP and further activated by formation of a pyrophosphate bond with CMP to form CDP-derivatives. Specific phosphatases remove the phosphate of phosphatidic acid to form diacylglycerol (Smith *et al.*, 1957), which displaces CMP from the activated intermediates to form the final products phosphatidylcholine and phosphatidylethanolamine. In liver and adipose tissue the diacylglycerol is also further acylated to form triacylglycerol for storage of fat. Studies of the interconversion of diacylglycerol and phosphatidic acid by kinases and phosphatases are an important area of investigation because of the branch point in metabolism between phospholipid synthesis and triacylglycerol storage. Purification of the yeast phosphatidic acid phosphatase followed by cloning of the *PAH1* gene encoding this enzyme (Han *et al.*, 2006) resulted in identifying a class of lipins as mammalian cell phosphatidic acid phosphatases (*PAP1-3*). This was a critical discovery because mice mutants in *lipin-1* displayed a low amount of liver and adipose triglyceride storage (Phan and Reue, 2005). The yeast discovery provided the means to identify the enzymatic activity of lipins.

All eukaryotes can convert phosphatidylethanolamine into phosphatidylcholine by trimethylation using *S*-adenosyl methionine as a donor (Figure 6). Mammalian cells express two enzymes (*PEMT1* and 2 gene products) that catalyze all three methylations while yeast express one enzyme (*PEM1/CHO2* gene product) catalyzing the first methylation (Ridgway and Vance, 1987; Vance and Ridgway, 1988; Cui *et al.*, 1993) and a second enzyme (*PEM2/OPI3* gene product) catalyzing the last two methylations (Summers *et al.*, 1988; Preitschopf *et al.*, 1993).

In mammalian cells phosphatidylserine is made in the endoplasmic reticulum membrane by two exchange enzymes

(Vance and Steenbergen, 2005) that catalyze the displacement by serine of the head group of either phosphatidylethanolamine (*PSS2* gene product) or phosphatidylcholine (*PSS1* gene product) (Figure 6). Phosphatidylserine is an important lipid in mammalian cells and is found in all of the multiple membranes of the cell. A primary role of phosphatidylserine is to organize protein molecular machines on membrane surfaces. In yeast, phosphatidylserine appears not to be important except as a means of making phosphatidylethanolamine or phosphatidylcholine in the absence of ethanolamine or choline in the growth medium.

The formation of phosphatidylcholine by methylation of phosphatidylcholine occurs primarily in the liver of mammals where high levels of phosphatidylcholine are needed to synthesize the serum lipoproteins necessary for transport of lipids from the liver to peripheral tissue. The pathway shown in Figure 6 is essential for new synthesis of phosphatidylcholine and phosphatidylethanolamine during starvation or fasting where the only source of ethanolamine and choline is through continuous displacement from phospholipids by serine derived from protein breakdown. This became evident in mice mutants lacking the methylation pathway that died within days on a diet lacking these two phospholipid precursors (Walkey *et al.*, 1998).

Synthesis of Non-Amine-Containing Phospholipids

The non-amine-containing phospholipids are phosphatidylinositol, phosphatidylglycerol, and cardiolipin (Figure 7). Phosphatidylinositol is synthesized in the endoplasmic reticulum membrane and is found in all membranes of eukaryotic cells. Phosphatidylglycerol and cardiolipin are synthesized exclusively in the inner mitochondrial membrane by gene products encoded by nuclear genes (as is the case with the *PSD1* gene product). Cardiolipin appears to be exclusively localized to the mitochondrial inner and outer membranes

Figure 6 Interconversion of phosphatidylserine, phosphatidylethanolamine, and phosphatidylcholine in yeast and mammalian cells. Genes encoding enzymes for each step are indicated next to the respective arrow. Gene names in red are the same for yeast and mammalian cells. Genes in blue or green denote a yeast or mammalian cell gene, respectively.

Figure 7 Synthesis of non-amine-containing phospholipids in eukaryotic cells. Genes encoding enzymes for each step are indicated next to the respective arrow. Gene names in red are the same for yeast and mammalian cells. Genes in blue or green denote a yeast or mammalian cell gene, respectively.

where it accounts for about 20% of mitochondrial phospholipids. Phosphatidylglycerol being a precursor to cardiolipin is only about 1% of mitochondrial phospholipids but is also found as an important component of lung surfactant where it is secreted by type II alveoli cells of the lung (Mason and Voelker, 1988). Phosphatidylglycerol suppresses viral and bacterial infection by blocking adhesion of these agents to the lung cell surface (Numata *et al.*, 2013).

CDP-diacylglycerol is synthesized from phosphatidic acid and CTP in yeast endoplasmic reticulum (Kelley and Carman, 1987) and mitochondria by the CDS1 (Shen *et al.*, 1996) and TAM41 (Tamura *et al.*, 2013) gene products, respectively. Mammalian cells appear to only contain CDP-diacylglycerol synthases in the endoplasmic reticulum (Paulus and Kennedy,

1960) encoded by the CDS1 (Weeks *et al.*, 1997) and CDS2 (Halford *et al.*, 1998) gene products. The mammalian cell enzymes are homologous to the *E. coli cdsA* gene (encodes CDP-diacylglycerol synthase) and yeast CDS1 gene products but not the yeast TAM41 gene product.

Phosphatidylinositol synthesis occurs by the displacement of CMP from CDP-diacylglycerol by inositol (Paulus and Kennedy, 1960; Fischl and Carman, 1983). Phosphatidylinositol is an essential lipid in eukaryotic cells. The polyphosphorylated phosphatidylinositols and inositols are important metabolic signaling and regulatory molecules (York *et al.*, 2001). They are also involved in the formation of the glycosylphosphatidylinositol (GPI) linkage that covalently tethers many proteins to the membrane surface (Tsai *et al.*, 2012).

Phosphatidylglycerophosphate synthesis takes place in the inner mitochondrial membrane of yeast (Chang *et al.*, 1998a) and mammalian cells (Kiyasu *et al.*, 1963; Kawasaki *et al.*, 1999) by the *PGS1* gene product following the bacterial pathway. However, there is little homology with the bacterial enzyme. As in bacteria, phosphatidylglycerophosphate is acted on by phosphatases to form phosphatidylglycerol primarily by the yeast *GEP4* (Osman *et al.*, 2010) and mammalian cell *PTPMT1* (Zhang *et al.*, 2011) gene products. There is no homology among the bacterial, yeast, and mammalian cell phosphatases.

Rather than a condensation of two phosphatidylglycerol molecules, cardiolipin synthesis in yeast (Schlame and Greenberg, 1997) and mammalian cells (Hostetler *et al.*, 1972) proceeds by a displacement of CMP from CDP-diacylglycerol by a molecule of phosphatidylglycerol. Due to the conversion of a pyrophosphate bond to a phosphoester bond, the equilibrium lies far in the direction of cardiolipin synthesis and is not reversible thus accounting for the low phosphatidylglycerol and high cardiolipin content of mitochondria. The *hCLS1* gene (Chen *et al.*, 2006; Houtkooper *et al.*, 2006; Lu *et al.*, 2006) and *CRD1* gene (Jiang *et al.*, 1997; Chang *et al.*, 1998b; Tuller *et al.*, 1998) encoding cardiolipin synthase in humans and yeast, respectively, have been identified and cloned.

Yeast null mutants in the *CRD1* gene accumulate the cardiolipin precursor phosphatidylglycerol (Chang *et al.*, 1998b) and are compromised but not completely lacking in oxidative

phosphorylation (Zhang *et al.*, 2002, 2005), the primary source of cellular metabolic energy. Mutants in the *PGS1* gene of yeast (Ostrander *et al.*, 2001b) and mammalian cells (Ohtsuka *et al.*, 1993a,b) display defects in mitochondrial morphology and complete loss of mitochondrial energy production. Therefore, the accumulated phosphatidylglycerol in the *CRD1* mutants appears to partially compensate for the lack of cardiolipin. Lack of or decreased levels of cardiolipin in eukaryotic cells results in failure of individual mitochondrial respiratory complexes to organize into higher order supermolecular complexes with an apparent reduction in their catalytic efficiency (Zhang *et al.*, 2002, 2005; Mileykovskaya *et al.*, 2012; Bazán *et al.*, 2013; Mileykovskaya and Dowhan, 2014).

In eukaryotic cells, composition of the acyl chains of cardiolipin does not reflect that of the general phospholipid pool. Given the four acyl chains of cardiolipin, there are potentially 81 compositional isomers of cardiolipin containing three different fatty acid species (Schlame, 2008). However, the combination of a cardiolipin monodeacylase (removes one fatty acid from cardiolipin) and the *TAZ1* gene product (a phospholipid transacylase that adds a fatty acid from another phospholipid) in all eukaryotic cells rapidly remodels newly synthesized cardiolipin to only a few of the possible isomers (Schlame, 2013). For instances, 90% of heart cardiolipin contains only linoleic acid (18 carbons with two unsaturated bonds). Respiratory function is compromised in pathological conditions or in the inherited disease Barth syndrome

Lipids	Phase	Molecular shape

(Schlame *et al.*, 2003) (TAZ1 mutant) where the levels of cardiolipin are abnormally low or where remodeling of the cardiolipin fatty acid composition is defective, respectively.

Roles of Phospholipids in Cell Function

The primary role of phospholipids is to form the lipid bilayer and permeability barrier of all cell membranes (Dowhan, 1997). Other lipid components such as cholesterol and sphingolipids are also important components of the membrane bilayer in eukaryotic cells. If one considers all these lipid classes and the diversity of individual species within each class resulting from the multiple fatty acids they contain, the liposome of cells ranges in the tens to hundreds of thousand individual species. This clearly outstrips the composition of the proteome. Therefore, if only one or two specific phospholipids are required to form a membrane bilayer, why are there so many lipid species (Dowhan, 1997)? The answer lies in the collective physical and chemical properties of a lipid bilayer made up of a mixture of lipid species and specific roles

for individual lipid species in defined cellular processes as partially alluded to earlier.

The ability of a glycerolipid to form a simple lipid bilayer depends mainly on the shape of the space occupied by the hydrophilic head group relative to the hydrophobic fatty acid domain (Cullis and de Kruijff, 1979; Sjolund *et al.*, 1989; Thurmond *et al.*, 1993). Lysophospholipids, phospholipids with short-chain fatty acids and detergents organize into micelles due to their inverted conical shape resulting from small hydrophilic domain relative to a large hydrophobic head group (Figure 8). The predominant fatty acids found in most membrane glycerolipids contain 16–18 carbons. The length and the physical state of the chains determine the width of the bilayer. Some variation in length is tolerated but these are usually minor fatty acid components. Some specialized membranes contain much longer but uniform lengths. The bonds within fatty acids at the *sn*-1 position are generally fully saturated while single and multiple unsaturated bonds are found in fatty acids that populate the *sn*-2 position. Hence, phospholipids and glycolipids with long-chain fatty acids and a cylindrical shape organize into extended sheets that become

Figure 9 Physical and chemical properties of glycerolipids. The charge character of the lipid head group and the phase properties are noted below each name. See Figure 1 for more details. Adapted from Dowhan, W., 2013. the two leaflets of the lipid bilayer. Each of the structures shown in [Figure 8](#) minimizes the exposure of hydrophobic surfaces to water.

The fluidity or the ability of lipid molecules or proteins to move laterally within the lipid bilayer increases with the degree of unsaturation of the fatty acid chains and the temperature. Bilayers of individual phospholipid species go through distinct physical transition from an ordered gel phase (L β) to a liquid crystalline phase (L α) as the temperature is raised ([Figure 8](#)). Each of these temperature-dependent transitions is lowered by increased unsaturated fatty acid content. Lipids in which the head group diameter is smaller than that of the hydrophobic domain assume a cone-like structure, which for pure lipid mixtures results in the hexagonal II or similar inverted structures, normally referred to as the non-bilayer phase. Unsaturated bonds in naturally occurring fatty acids are in the *cis* configuration, which increases the space they occupy and their mobility at any given temperature. For non-bilayer prone lipids the degree of unsaturation of their fatty acids and the temperature is a factor determining the transition temperature from the bilayer to non-bilayer phase. As an example all species of phosphatidylethanolamine tend to organize into bilayers at low temperature, but will transition to the non-bilayer phase as the temperature is raised. This transition temperature is inversely related to the degree of unsaturation of the fatty acids.

The mixture of lipids in natural membranes is maintained in the L α phase and the content of bilayer to non-bilayer prone lipids is adjusted either by changing the lipid head group or fatty acid composition in those organisms normally exposed to variations in temperatures. A secondary consequence of the presence of non-bilayer prone lipids such as phosphatidylethanolamine, cardiolipin, or monoglucosyl diacylglycerol in biological membranes is that their conical shape introduces lateral stress within the bilayer, which appears to be important for the function of many membrane-associated proteins. The CDP-choline: diacylglycerol phosphotransferase is a cytoplasmic protein, but in response to an increase in membrane non-bilayer prone lipids, it partially inserts into one leaflet of the lipid bilayer where it is activated to synthesize the bilayer prone phosphatidylcholine. Such association appears to be energetically driven by relief of lateral stress upon membrane association ([Cornell and Northwood, 2000](#); [Kitos et al., 2006](#); [Chong et al., 2014](#)). A summary of the physical and chemical properties of several glycerolipids can be found in [Figure 9](#).

Charge density of the membrane surface is a function of the ratio of net anionic lipids such as phosphatidylserine, phosphatidylinositol, phosphatidylglycerol, and cardiolipin to net neutral lipids such as phosphatidylcholine, phosphatidylethanolamine, and the glycolipids. As an example of the importance of surface charge, the orientation of membrane protein transmembrane domains with respect to the plan of the lipid bilayer is determined by the charge nature of the protein extramembrane domains and the net negative charge density of the lipid head groups exposed at the membrane surface ([Bogdanov et al., 2013](#)). Some protein functions are dependent on a specific lipid head group as well as the extent of unsaturation of the fatty acid chains. An example is the mammalian cardiolipin synthase, which both *in vivo* and *in vitro* requires CDP-diacylglycerols with at least one

unsaturated fatty acid in order to be a substrate while the phosphatidylglycerophosphate synthase is insensitive to the fatty acid composition ([Ostrander et al., 2001a](#)).

Introduction

Cholesterol is a major component of cell membranes and a precursor to many important biological molecules. Since the discovery of cholesterol from gallstones in the eighteenth century, it has been a molecule of great interest and has been studied extensively. As a result, 13 Nobel Prizes have been awarded to researchers who contributed to the study of cholesterol, its chemistry, biochemistry, physiological role, and its clinical significance. Cholesterol metabolism has complex regulatory mechanisms and new functions for this molecule in cell biology and disease processes are being uncovered even hundreds of years after its initial discovery.

There is considerable evidence demonstrating that cholesterol is indispensable for normal functioning of a cell. Cholesterol is important for many biological processes and its accumulation or depletion can be detrimental to the body as evidenced by multiple disorders identified in animal models and in humans with defective cholesterol homeostasis. Due to the fine balance that exists between its essential role in normal biological function and its role in disease, complex regulatory mechanisms that strictly monitor and regulate the synthesis, uptake, transport, and elimination of cholesterol have evolved. This regulation is achieved by feedback regulatory mechanisms involving a family of transcriptional factors, cholesterol synthesis enzymes, sterol-sensing proteins, and lipoprotein receptors.

Cholesterol has important functions in membrane dynamics, bile acid synthesis, signal transduction, myelin sheath composition, and steroid hormone formation (Ikonen, 2008; Dowhan *et al.*, 2008). In humans, cholesterol is obtained from both the diet and endogenous synthesis. Cholesterol is synthesized endogenously by many tissues but the liver is the predominant site of cholesterol synthesis. Cholesterol synthesis progresses through a complex pathway that contains many enzymes and is tightly regulated in many steps. The rate of endogenous synthesis of cholesterol depends on a number of factors including the amount of cholesterol uptake from diet. A feedback mechanism exists that allows the liver to sense plasma cholesterol concentrations and regulate cholesterol biosynthesis in cells. Defects in lipid and cholesterol metabolism have been associated with conditions such as cholelithiasis, Smith-Lemli-Opitz syndrome (SLOS), Tangier disease, cancer, neurological conditions, and, most commonly, several cardiovascular disorders including atherosclerosis (Maxfield and Tabas, 2005; Orth and Bellosta, 2012). A detailed understanding of important players in the cholesterol synthesis pathway and cholesterol homeostasis processes is fundamental to understanding and treating these cholesterol-associated disorders. The structure, function, cellular cholesterol homeostasis, and the role of cholesterol in several diseases are discussed in detail below.

Structure

The structure of cholesterol was elucidated in the twentieth century by the work of many scientists including Nobel Laureates Otto Diels, Robert Robinson, Heinrich Wieland, Adolf Windaus, and Leopold Ruzicka (Brock, 2000). Cholesterol belongs to the family of polycyclic compounds known as sterols. This 27-carbon structure has rigid planar rings and a flexible tail (Figure 1). Cholesterol is comprised of four hydrocarbon rings, a hydroxyl group attached to C3 and an eight-carbon tail. The four planar rings contribute to the hydrophobicity of the molecule while the hydroxyl group is hydrophilic, making cholesterol amphipathic (Bloch, 1983). Although cholesterol is slightly polar, it is highly insoluble in water. In the cell membrane cholesterol orients with the hydrophobic rings facing the fatty acid chain of the phospholipid and the polar hydroxyl group facing the aqueous layer. While the hydroxyl group confers polarity to the molecule allowing it to form a part of the cell membrane, it is also important as a site for esterification of cholesterol. These chemical properties allow cholesterol to form an integral part of the cell membrane and perform its functions effectively, but interestingly, the same properties make it toxic to cells in free form.

Cholesteryl Esters

Most of the cholesterol in humans exists in ester form. Cholesterol converted into cholesteryl ester can be stored and transported more efficiently. Since cholesteryl esters are more hydrophobic than cholesterol, they can be packaged inside the hydrophobic core of lipoproteins and transported throughout the body (Ginsburg *et al.*, 1984). Esterification of cholesterol is required for both delivery of cholesterol to the tissues and for removal of cholesterol from peripheral tissues. Cholesterol esterification is one of the several mechanisms cells use to prevent accumulation of free cholesterol that is toxic to cells (Tabas, 2002). Free cholesterol is esterified in liver and plasma by specialized mechanisms. The enzymes lecithin:cholesterol acyltransferase (LCAT) and acyl-coenzyme A:cholesterol acyltransferase (ACAT) catalyze the esterification of cholesterol (Peelman *et al.*, 2000; Chang *et al.*, 1997). Another enzyme central to cholesterol homeostasis is cholesteryl ester transfer protein (CETP). CETP plays an important role in transferring cholesteryl esters and triglycerides between high-density lipoprotein (HDL) and low-density lipoprotein (LDL) particles (Barter, 2003). Lysosomal acid lipase is an enzyme that is required for breaking down cholesteryl esters into free cholesterol. Deficiency of this enzyme is associated with disorders such as Wolman disease and cholesteryl ester storage disease characterized by abnormal accumulation of cholesteryl ester in liver eventually leading to chronic liver disease (Fouchier and

Figure 1 Structure of cholesterol and other steroids.

Defesche, 2013). Proper formation, transport, and hydrolysis of cholesteryl esters are essential in overall cholesterol homeostasis in the body.

Cholesterol in Cell Membranes

Cholesterol levels within the cell membrane influence the biophysical properties of the membrane and play a critical role in cell membrane ordering, permeability, phase transitions, and in maintaining cell membrane integrity. The plasma membrane is made up of phospholipid bilayer, proteins, cholesterol, glycoproteins, and glycolipids (Figure 2). Cholesterol is not arranged uniformly throughout the plasma membrane, but is found in varying concentrations. The hydroxyl group of cholesterol in phospholipid bilayer is oriented toward the hydrophilic head of the phospholipids in the membrane. At high temperatures, cholesterol reduces phospholipid movement and prevents the membrane from becoming too fluid or permeable. However, at low temperature, cholesterol prevents crystallization of membranes that can occur due to close packing of fatty acid tails. Cholesterol has also been shown to be associated with sphingolipids to form lipid rafts (George and Wu, 2012; Brown and London, 2000). These rafts have an important role in protein interaction during cell signaling (Lemaire-Ewing *et al.*, 2012; Simons and Toomre, 2000; George and Wu, 2012). Moreover, cholesterol has been recognized as an essential modulator of sonic hedgehog signaling. It is also required for the formation of clathrin-coated pits in cell membranes during endocytosis. There is direct evidence that depletion of cholesterol in the

Figure 2 Cholesterol in plasma membrane.

membrane inhibits the internalization of clathrin-coated pits (Subtil *et al.*, 1999). Thus, cholesterol not only alters the properties of the cell membrane but plays an active role in the functional aspect of the cell membrane.

Cholesterol Biosynthesis

Cholesterol synthesis, also called cholesterologenesis, is a multistep enzymatic biosynthetic process that begins with acetyl-coenzyme A. A simplified schematic of the pathway that displaces the most important steps is shown in Figure 3. Cholesterol synthesis takes place in the cytoplasm and in the endoplasmic reticulum (ER). The first step in the pathway catalyzed by 3-hydroxy-3-methylglutaryl (HMG)-CoA synthase (HMGCS) occurs in the cytosol while the subsequent steps occur in the ER. Thus, the ER is the main site of cholesterol synthesis (Simons and Ikonen, 2000). Cholesterol synthesis begins with acetyl-coenzyme A derived from mitochondria and transported to the cytosol. One molecule of acetyl-coenzyme A and one molecule of acetoacetyl-CoA are

Figure 3 Cholesterol biosynthesis pathway.

converted to HMG-CoA. HMG-CoA is then reduced to mevalonate by HMG-CoA reductase (HMGCR). Mevalonate is further phosphorylated to isopentenyl pyrophosphate, which is converted to geranyl pyrophosphate. Condensation with another isopentenyl pyrophosphate yields farnesyl pyrophosphate. Squalene synthase catalyzes the condensation of two molecules of farnesyl pyrophosphate to yield squalene. Squalene is then cyclized to form lanosterol. Finally lanosterol is converted to cholesterol in 19 more reactions.

HMGCR is the rate-limiting enzyme of the pathway. It is tightly regulated at transcriptional and posttranscriptional levels. Mechanisms such as phosphorylation–dephosphorylation, feedback from sterol and non-sterol metabolites of the pathway, and ubiquitination control the activity and levels of HMGCR. This enzyme is a pharmacological target of a class of drugs called statins, which are commonly used to lower cholesterol by reducing cholesterol biosynthesis. Statins are competitive inhibitors of HMGCR enzyme.

The cholesterol biosynthesis pathway yields several molecules as intermediates that are essential for other biological pathways. Farnesyl and geranylgeranyl membrane anchors are important for signaling proteins that regulate progression through cell cycle (Edwards and Ericsson, 1999). Ubiquinone and dolichols are other intermediates that have roles in electron transport and synthesis of glycoproteins, respectively. Cholesterol can be further modified into steroid hormones as well as vitamin D.

Regulation of Cholesterol Biosynthesis

The complex regulation of cholesterol biosynthesis takes place at several levels. The rate of synthesis is highly responsive to cellular level of cholesterol. There exists a feedback regulation

mediated by changes in HMGCR. High cholesterol levels cause reduction in transcription of *HMGCR* gene, leading to the reduction in the amount of HMGCR (messenger RNA) mRNA. HMGCR activity is also regulated through phosphorylation. AMP (adenosine monophosphate)-dependent protein kinase (AMPK) catalyzes the phosphorylation and inhibition of the enzyme (Motoshima *et al.*, 2006). Various cholesterol metabolites such as oxidized derivatives of cholesterol as well as cholesterol biosynthesis intermediates such as mevalonate and farnesol are additional components of the negative feedback loop that regulates the levels of HMGCR (Correll *et al.*, 1994). Cholesterol can also induce ubiquitination and degradation of HMGCR. Increases in cellular cholesterol concentrations triggers binding of HMGCR to the ER membrane proteins Insig-1 and Insig-2. This binding leads to the recruitment of gp78, the ubiquitin ligase that leads to ubiquitination of the enzyme. In this manner, HMGCR is marked for degradation and transported to proteasomes for degradation (DeBose-Boyd, 2008).

A complex of proteins that sense cellular cholesterol levels also regulates the rate of cholesterol synthesis. Sterol response element binding protein (SREBP), the SREBP cleavage activating protein (SCAP), and two SREBP-specific proteases (S1P and S2P) are the key components of this pathway (Horton *et al.*, 2002; Bengoechea-Alonso and Ericsson, 2007). SREBP precursor proteins are embedded in the membrane of ER. The N-terminal domain of SREBP acts as a transcription factor, whereas the C-terminal domain interacts with C-terminal domain of another ER protein SCAP, which contains a sterol-sensing domain. As shown in Figure 4, when sterol levels are high, SCAP interacts with ER membrane protein, insulin regulated protein (Insig) (Yang *et al.*, 2002). Association with Insig leads to the retention of SREBP–SCAP complex in the ER (Yang *et al.*, 2002). When sterol levels are low, SCAP and Insig do not interact, which leads to a conformational change in

Figure 4 SREBP and SCAP in transcriptional control of cholesterol synthesis.

SCAP (Brown *et al.*, 2002). The SREBP–SCAP complex then translocates from ER to Golgi apparatus (Figure 4). Two proteases, S1P and S2P, act on SREBP in the Golgi apparatus (Nohturfft *et al.*, 2000). SREBP is first cleaved by protease S1P, yielding a product that then acts as a substrate for protease S2P. This cleaved SREBP is then released to the cytosol and travels to the nucleus where it binds to sterol response element (SRE) DNA sites resulting in increased transcription of several genes involved in cholesterol synthesis pathway (Bengoechea-Alonso and Ericsson, 2007).

Cellular Cholesterol Homeostasis

In addition to intracellular synthesis, cholesterol can also enter the cells through uptake of cholesterol-containing lipoproteins from plasma. A simplified schematic of cholesterol homeostasis is presented in Figure 5. Cholesterol from diet is absorbed in the intestine, solubilized in micelles, and transported to the periphery packaged in the form of chylomicrons along with triglycerides (Wang, 2007). The enzyme lipoprotein lipase interacts with chylomicrons and hydrolyzes triglycerides to release fatty acids. The resulting chylomicron remnants enter hepatocytes by binding to apolipoprotein E receptors. Cholesterol is subjected to endocytosis and is either converted to bile acids, secreted into circulation, esterified, or packaged into very low-density lipoprotein (VLDL) particles. These VLDL particles containing cholesterol and triglycerides are secreted into circulation. Interaction of VLDL particles with lipases results in change in the composition of these particles. These particles contain less triglycerides and all apolipoproteins are lost except apolipoprotein B (ApoB). These modified particles are called LDLs. LDL particles are responsible for transporting cholesterol to the periphery.

LDL particles are mostly composed of cholesterol esters. Cells that require cholesterol express receptors that recognize and bind LDL particles resulting in receptor-mediated

endocytosis. LDL particles and their receptors have an important role in cholesterol homeostasis (Go and Mani, 2012). Genetic mutation in the LDL receptor is associated with a condition called familial hypercholesterolemia, which is associated with increased atherosclerosis and heart disease. LDL-derived cholesterol is shown to inhibit *HMGCR* gene transcription by inhibiting SREBP pathway (Brown and Goldstein, 1980). Increased LDL cholesterol leads to the reduction of synthesis of LDLR through negative feedback mechanism. When the cholesterol level in cells is low, more LDLRs are produced that help take up LDL from plasma. Along with inhibiting *HMGCR*, statins upregulate LDLR resulting in clearing of LDL from the circulation. These LDLRs undergo endocytosis taking LDL inside the cell through endosome and are later released from endosome and are either degraded or released back to the surface (Ikonen, 2008). Due to the cellular toxicity of free cholesterol, excess free cholesterol must be esterified (by the enzyme ACAT) and packaged in lipid droplets (Chang *et al.*, 1997).

LDL particles undergo a range of modifications. Oxidized LDL particles are specifically targeted for uptake by scavenger receptors found in macrophages. These help reduce the amount of plasma LDL cholesterol and return them to the liver in the form of HDL, another lipoprotein particle, via a process called reverse cholesterol transport. HDL particles play a critical role in reverse cholesterol transport where cholesterol is returned to the liver from the periphery. Nascent HDL particles interact with cholesterol transporter proteins on the cell surface, ATP-binding cassette, sub-family A, member 1 (ABCA1), and ATP-binding cassette, sub-family G, member 1 (ABCG1), and accept cholesterol. The enzyme LCAT in HDL converts free cholesterol to cholesteryl esters and stores them in the HDL core. A defect in *ABCA1* gene is associated with Tangier disease, which is associated with very low levels of HDL and high risk of atherosclerosis. Cholesterol transported back to the liver is either recycled, stored, or converted to bile acids.

Nuclear receptors such as liver X-receptors (LXR), farnesoid X-receptor (FXR), and peroxisome proliferator-activated

Figure 5 Overview of cholesterol homeostasis.

receptor γ (PPAR γ) are crucial in cholesterol homeostasis. LXRs are activated by cholesterol derivatives, oxysterols. LXRs are transcription factors and regulate the expression of important genes such as *ABCA1*, *ABCG1*, and *ApoE* important in the process of reverse cholesterol transport (Laffitte *et al.*, 2001; Beyea *et al.*, 2007). FXRs play a role in bile acid metabolism and in regulation of cholesterol removal from body. The ability of these nuclear receptors to affect cholesterol metabolism makes them an attractive therapeutic target for treatment of metabolic diseases associated with dyslipidemia.

Cholesterol in Brain

The brain contains approximately one-fourth of the total amount of cholesterol in the body, making it the most cholesterol-rich organ. Cholesterol is a major component of the myelin sheath and is crucial for proper brain development (Dietschy and Turley, 2001). A distinct pool of cholesterol is maintained in the brain by local *de novo* synthesis. The blood-brain barrier prevents the exchange of lipoproteins in the circulation, thus the brain must maintain its own cholesterol transport system. In adult brain, astrocytes synthesize most of the cholesterol and send them to neurons in ApoE-containing lipoproteins particles. Cholesterol released from astrocytes through ABCA1 and ABCG1 transporters are shuttled to neurons and taken up by receptor-mediated endocytosis via LDLR family receptors.

Unlike other peripheral organs, cholesterol is recycled at a very high rate in the brain. As a result, the half-life of cholesterol in adult brain is about five years (Björkhem *et al.*, 1998). While most of the cholesterol is recycled, the brain also excretes some cholesterol in the form of 24(S)-hydroxycholesterol. Cholesterol is converted to 24(S)-hydroxycholesterol by the CYP46 (cholesterol 24-hydroxylase) enzyme. As evident from numerous studies, cholesterol metabolism in the brain is independent of that in rest of the body (Björkhem *et al.*, 1998; Dietschy and Turley, 2001). The importance of separate cholesterol regulatory mechanisms in brain is still not completely understood. However, tight regulation of cholesterol synthesis in brain appears to be critical and defects in cholesterol metabolism have been implicated in many neurological disorders.

Cholesterol in Diseases

Many pathological conditions are associated with abnormal cholesterol levels or impaired cholesterol metabolism in the body. Some of these are briefly discussed below.

Cardiovascular diseases: Elevated cholesterol levels are associated with cardiovascular conditions such as atherosclerotic plaque formation, stroke, and myocardial infarction. Formation of atherosclerotic plaque is an intricate process involving inflammation and lipid deposition that eventually narrows the arteries which results in luminal obstruction.

Hypercholesterolemia is a well-established risk factor for the incidence of atherosclerosis and its pathologic complications. Modified LDL is taken up by mature macrophages in the artery. These macrophages accumulate in the subendothelial space and become cholesterol-laden foam cells that eventually harden and become plaques. Statins (inhibitors of HMGCR) that effectively lower plasma cholesterol are the most commonly prescribed drug.

Cholesterol gallstone disease (Cholelithiasis): Gallstones are masses of cholesterol crystals, calcium bilirubinate, and proteins. Gallstones are formed as a result of excess cholesterol in bile or due to insufficient bile acids. This condition is highly prevalent in developed countries. Dyslipidemia is one of the major risk factors of cholesterol gallstones.

Familial hypercholesterolemia: Mutations within the low-density lipoprotein receptor gene are one of the major causes of familial hypercholesterolemia. Due to the defect in this receptor, LDL accumulates in the plasma leading to enhanced atherosclerosis.

Tangier disease: Mutations in the gene encoding the cholesterol transporter ABCA1 result in very low levels of HDL particles in blood (Bodzioch *et al.*, 1999). Tangier disease is inherited as an autosomal recessive trait. There is excessive accumulation of cholesterol in several parts of the body due to impaired reverse cholesterol transport and the disease is associated with increased atherosclerosis.

SLOS: SLOS is a developmental disorder characterized by several physical, mental, and behavioral abnormalities related to deficiency of cholesterol synthesis. DHCR7 codes for the enzyme involved in the last step in cholesterol synthesis. Mutation in this gene causes the buildup of the 7-dehydrocholesterol metabolite, resulting in insufficient cholesterol synthesis; both combined are responsible for the multiple developmental disorders.

Neurological disorders: Defects in cholesterol metabolism in the brain have been associated with many neurological disorders such as Alzheimer's disease, Parkinson's disease, Huntington's disease, Niemen-Pick disease, and SLOS (Vance, 2012). The complexity of these diseases together with very limited knowledge of cholesterol metabolism in brain has proved to be a major challenge for scientists trying to study the pathology of the disease.

Steroids

Cholesterol is the precursor of numerous sterol molecules such as oxysterols, bile acids, and steroid hormones. These cholesterol metabolites function as activators of nuclear receptors, regulate expression of genes in lipid and fat metabolism, have important function in bile acid synthesis and steroid hormone production, and are required for the transport of sterols from peripheral tissues such as brain to the liver.

Bile acids are oxidized derivatives of cholesterol. These are amphipathic molecules required for processing of dietary fat and for maintaining cholesterol homeostasis. Conversion of cholesterol into bile is the only mechanism of cholesterol excretion from the body. Bile is formed in the liver by the action of many enzymes and cholesterol 7- α hydroxylase (CYP7A1) is the rate-limiting enzyme for bile acid synthesis (Jelinek *et al.*, 1990).

Cholesterol also serves as a precursor for all steroid hormones. These hormones regulate many important physiological processes such as stress response, cognition, ion balance, secondary sexual characteristics, electrolyte balance, and carbohydrate metabolism. Steroid hormones are produced primarily in response to trophic hormones in several steroidogenic tissues including adrenal cortex, testes, ovary, placenta, and brain.

During steroid synthesis, cholesterol in the cell is transported to the mitochondria where the enzyme Cyp11 converts it to pregnenolone, which is the common precursor of all steroid hormones (Figure 6; Miller and Auchus, 2011). Since cholesterol cannot travel from outer to inner mitochondrial membrane due to its hydrophobicity, the delivery of cholesterol to the inner membrane is the rate-limiting step in steroidogenesis. The enzyme steroidogenic acute regulatory protein (STAR) regulates this rate-limiting step by facilitating the transfer of cholesterol into the inner membrane of mitochondria (Stocco, 2001; Miller and Auchus, 2011).

Testosterone, progesterone, estradiol, cortisol, and aldosterone are five major classes of steroids. These hormones are all derived from pregnenolone and control a wide variety of physiological processes. Progesterone is required for maintenance of pregnancy, follicular growth, and ovulation and is produced by ovarian cells and corpus luteum (Graham and

Figure 6 The biosynthetic pathway of steroid hormones.

Clarke, 1997). Cortisol is produced by adrenal cortex and has a number of diverse functions including modulating blood pressure and Na⁺ uptake, inflammation, glucose metabolism, and stress response. Testicular leydig cells produce testosterone, which is critical for the development and maintenance of male sex characteristics and functions. Similarly, estrogen, produced by ovary, is required for the maintenance and development of female sex characteristics and is also found to be important for maintaining bone integrity. Finally, aldosterone, produced in adrenal cortex, regulates blood pressure and enhances sodium reabsorption in the kidney and sweat glands (Müller, 1995). Apart from these classical steroids, neurosteroids are another class of steroids synthesized in the brain. These steroids are found to play a critical role in neuronal survival, plasticity, and functions (Sarkar *et al.*, 2011; Di Michele *et al.*, 2013; Tsutsui, 2012).

Glycolipids

AH Merrill Jr. and MN Vu, Georgia Institute of Technology, Atlanta, GA, USA

© 2016 Elsevier Inc. All rights reserved.

Introduction

Depending on how you look at them, glycolipids are either enchanting biomolecules, being comprised of the most structurally diverse and complex families of compounds (carbohydrates and lipids), or they seem so mind-bogglingly complicated that you can hardly bear to think about them. To help minimize the reader's inclination toward the latter attitude, this article will summarize the types of compounds that fall in this category of biomolecules and clarify the fairly straightforward structural features that define them. Then, the review will illustrate with one category, the glycosphingolipids, how such structural complexity is generated biochemically and how thinking about the compounds in pathway maps simplifies the complexity somewhat. Although the enormity of this field precludes discussion of every type of glycolipid, the terms and concepts covered in this review should help the newcomer feel less intimidated about approaching them, and perhaps even those with knowledge about glycolipidology will be surprised by how many different ways nature has married these two families of compounds.

Definition of 'Glycolipid' and Subcategories of Glycolipids

The term 'glyco-' refers to the presence of a 'glycan' as part of the compound, which is defined by the glossary from Essentials of Glycobiology (Varki *et al.*, 2009) (available online) as 'a generic term for any sugar or assembly of sugars, in free form or attached to another molecule' and is often used interchangeably with carbohydrate or saccharide.

The complexity of glycobiology arises from the existence of many different carbohydrates (glucose, galactose, etc.) multiplied by the many ways they can be combined in polysaccharides. If all of the theoretical combinations of these compounds were produced, the numbers would be staggering because it has been estimated that six different hexoses can be combined to form $>10^{12}$ different hexasaccharides, $\sim 10^{15}$ heptasaccharides, $>10^{18}$ octasaccharides, and nearly Avogadro's number for nonasaccharides (Laine, 1994).

The term 'lipid' refers to the portion of these compounds that (as has been summarized by the LIPID MAPS Consortium) (Fahy *et al.*, 2005) '... have been loosely defined as biological substances that are generally hydrophobic in nature and in many cases soluble in organic solvents...' Lipids are, thus, also structurally diverse and have been subdivided into eight categories: fatty acyls, glycerolipids, glycerophospholipids, sphingolipids, sterol lipids, prenol lipids, saccharolipids, and polyketides. At least a few of the lipids from each of these categories have been found as glycoconjugates in nature, and for some categories (such as sphingolipids) the discrete molecular subspecies for the lipid backbone probably numbers in the thousands.

Thus, this review considers glycolipids to encompass all of the compounds that are comprised of a carbohydrate and a lipid. The term lipid-linked oligosaccharide (LLO) is sometimes also used for glycolipids, but is most often applied to the particular case of the dolichol pyrophosphate-linked oligosaccharide that is transferred to asparagine residues of nascent polypeptides in the endoplasmic reticulum during N-linked glycoprotein biosynthesis (this will be discussed under prenol lipids below).

Overview of the Different Types of Glycolipids Found in Nature

There are several useful web sites for glycolipids that provide information about their structures and nomenclature, tools to facilitate their analysis, metabolic pathways and genes, and sometimes updates and notices of upcoming conferences. Of note are the American Oil Chemistry Society (AOCS) Lipid Library, Glycoforum, LIPID MAPS, and the Consortium for Functional Glycomics. In an attempt to obtain uniformity in nomenclature and the way to display the structures of these compounds, the LIPID MAPS lipid classification system (Fahy *et al.*, 2005) has been adopted by some journals, and the website provides downloadable structure diagrams for many glycolipids (when used in this review, the LIPID MAPS number, 'LM____,' has been provided). Other 'toolboxes' have recently been summarized (Campbell *et al.*, 2014), and the list continues to grow as this field does. It is also helpful sometimes to consult the glycolipid nomenclature recommendations of the International Union of Pure and Applied Chemistry and the International Union of Biochemistry and Molecular Biology (IUPAC-IUB) Joint Commission on Biochemical Nomenclature. This review does not attempt to cover all the structural variations for all organisms, which would require a much longer treatise, but to illustrate some of the major features and the fascinating differences among these compounds.

Glycoglycerolipids

The compounds termed glycoglycerolipids typically have a carbohydrate connected to a 1,2-diacyl-*sn*-glycerol moiety (as shown in the prototype in Figure 1) where R1 and R2 are typically long-chain fatty acids in ester linkage to the glycerol backbone. In some cases, one or more of the glycerol hydroxyls is linked to a fatty alcohol in ether linkage, as shown for seminolipid in the bottom example in this figure. Since glycerol *per se* does not have stereochemistry, the '*sn*' designation of glycerolipids (standing for 'stereospecific numbering') takes into account that stereoisomers are generated once asymmetric substituents have been added to the hydroxyls. The structures shown in Figure 1 and elsewhere in this review are numbered following this convention. Likewise, commonly accepted names and abbreviations have been used for the fatty acids and fatty alcohols (see online LIPID MAPS

Glycoglycerolipids

Prototype:

Examples:

Figure 1 Representative structures of glycoglycerolipids. A general prototype for these compounds is shown in the upper diagram with R1 and R2 representing the alkyl chains of fatty acids attached to the glycerol backbone at these two positions and at position 3 is attached the glycan. The abbreviations for the carbohydrates shown are: Gal, galactose; Glc, glucose; GlcA, glucuronic acid; SQ, sulfoquinovose. Examples of specific compounds are shown below with common and full names, and where the structures were downloaded from the LIPID MAPS Website, with the 'LM' number.

Lipid Classification system); i.e., for the first number to designate how many carbon atoms are in the alkyl chain followed by a slash, colon or semicolon and a second number for how many double bonds are present. Unless otherwise stated, it is assumed that the double bonds are *cis*- (Z, in the E/Z designation of *trans/cis* double bond configurations). Fatty acids can have other features, such as hydroxyl-, methyl-, cyclopropyl- and other groups, and a somewhat unusual, but interesting, backbone is seen in 15-O-linoleoyl-digalactosyldiacylglycerol (Figure 1, middle), which was isolated from oat seeds. Its lipid diacylglycerol backbone has a hydroxyl-fatty acid with a third fatty acid in ester linkage to this hydroxyl – a feature found in so-called 'estolides.'

The carbohydrate that is attached to the 3-hydroxyl of glycerol can be in α - or β -glycosidic linkage (β -linked galactose,

abbreviated Gal, is shown in all of the examples in Figure 1) and this type of monosaccharide is usually abbreviated 'MGDC' for monogalactosyldiglyceride. Other carbohydrates include those to the right of the prototype (glucose, Glc; glucuronic acid, GlcA; and sulfoquinovose, SQ) as well as mannose, rhamnose and aminosugars (not shown). Di- and polysaccharides are designated by the type of linkage (α - or β -) and location, with the anomeric carbon numbered 1 followed by the site of attachment to the neighboring carbohydrate (e.g., 1 $\rightarrow$ 2, 1 $\rightarrow$ 3, 1 $\rightarrow$ 4, or 1 $\rightarrow$ 6). This nomenclature is shown for the digalactosyldiglyceride (DGDG) in Figure 1. In some cases, hydroxyls of the carbohydrates are esterified with fatty acids.

Glycoglycerolipids are commonly found in plants, algae and bacteria, and are the predominant lipids in chloroplasts of

many organisms (Holzl and Dormann, 2007; Zhang *et al.*, 2014). They have attracted interest for their potential use as antiviral, antitumor, and anti-inflammatory agents. Glycoglycerolipids are less prevalent in mammals, with the exception of testis where seminolipid (the bottom structure of Figure 1) has been reported to comprise more than 90% of total glycolipid (Honke, 2013).

Glycophosphoglycerolipids

For this article, the term glycophosphoglycerolipids is used to define the lipids that are comprised of a phosphatidyl-backbone (i.e., 1,2-diacylglycerol 3-phospho-) (or in some cases, O-alkyl rather than acyl) for the lipid moiety and a carbohydrate headgroup attached in a phosphodiester linkage, as

shown in Figure 2. The AOCS Lipid Library describes a similar category and notes that the term conveniently describes these compounds even if it does not appear to be widely used. The Library also notes that there are compounds that can be referred to as 'phosphoglycerolipids' because they are glycolipids in which the sugar moiety is phosphorylated, but that is distinct from the compounds discussed here.

The most widely known glycophosphoglycerolipids are undoubtedly the inositol phospholipids (Figure 2), which are ubiquitously distributed in Eukarya, most of Archaea, and some Bacteria (Michell, 2013). The lipid backbones differ considerably between eukaryotes/bacteria (which are primarily 1,2-diacylglycerols) versus Archaea, which have two isoprenoid chains attached to positions 2,3 of glycerol via

Glycophosphoglycerolipids

Prototype: 1,2-diacyl-3-phospho- β -D-glycan (or phosphoglycan)

Examples:

Figure 2 Representative structures of glycophosphoglycerolipids. A general prototype for these compounds is shown in the upper diagram with R1 and R2 representing the alkyl chains of fatty acids attached to the glycerol backbone at these two positions and at position 3 is attached the glycan. Also shown is the phytanyl backbone that is found in archaeal glycophosphoglycerolipids and a lipid used as an intermediate in phosphoglycerolipid biosynthesis (CDP-diacylglycerol) that falls under this category because the CDP-moiety contains a sugar. Where a structure was downloaded from the LIPID MAPS Website, the 'LM' number has been given.

ether bonds, as shown by 2,3-diphytanyl-*sn*-glycerol (Morii *et al.*, 2014) in Figure 2. Much of the interest in inositol phospholipids revolves around two further structural modifications: (1) phosphorylation of the inositol at positions 3, 4, and 5 in different combinations and the attendant biological functions of these compounds in normal cell behavior and disease (Michell, 2013; Balla, 2013); and (2) extension of the glycan headgroup with glucosamine, mannose, and phosphoethanolamine groups to form a 'Glycosylphosphatidylinositol Anchor' (GPI) for some categories of membrane bound proteins (Paulick and Bertozzi, 2008).

Phosphatidylglucose (Figure 2) is another glycosphingolipid that has been isolated from several mammalian sources, with the interesting feature that the lipid backbone from neutrophils has saturated fatty acyl chains (C18:0/C18:0 and C18:0/C20:0), whereas fetal rodent brain has 1-stearyl-2-arachidoyl- as shown in Figure 2. A portion has an acetylated glucose (6-O-acetylglucose), as is also shown

(Ishibashi *et al.*, 2013). The functions of these lipids are still being elucidated.

The glycosphingolipid category also includes compounds with a pyrophosphate linkage to a carbohydrate-containing headgroup, as seen in CDP-diacylglycerol, a biosynthetic intermediate for phospholipid biosynthesis by many organisms (Figure 2).

Glycosphingolipids

Glycosphingolipids are defined as glycolipids with lipid backbones called 'ceramides' that are comprised of sphingoid bases (hence, the origin of the 'sphingo' of sphingolipids) that are N-acylated with a long- or very-long-chain fatty acid as shown in Figure 3 (Merrill, 2011). Although most depictions of sphingolipids show sphingosine as the backbone (as in this prototype), a large number of structural variations have been reported (Pruett *et al.*, 2008), particularly with respect to alkyl chain length, number and position of double bonds and

Glycosphingolipids

Prototype: Lactosylceramide

Examples:

Figure 3 Representative structures of glycosphingolipids. A general prototype for these compounds is shown in the upper diagram using lactosylceramide. The other examples also illustrate structural variations, and for further examples see Figures 4, 10 and 11. Where a structure was downloaded from the LIPID MAPS Website, the 'LM' number has been given.

number of hydroxyls. The shorthand abbreviations for sphingoid base are: (1) to depict the number of hydroxyls by 'd' (dihydroxy, as in sphingosine), 't' (trihydroxy, which is most commonly found in 4-hydroxysphinganine, or 'phyto-sphingosine' – a major species in epithelial cells and skin, plants and fungi) and 'm' (monohydroxy) (1-deoxy-sphingoid bases are interesting because they are made when serine palmitoyltransferase (SPT) utilizes alanine instead of serine (Zitomer *et al.*, 2009; Penno *et al.*, 2010), but lacking the usual site of glycosylation, they are probably not backbones for mammalian glycolipids); (b) to depict the number of carbon atoms and double bonds in a manner similar to fatty acids (i.e., 18:1 for the 18-carbon atoms and single double bond of sphingosine) – sphingoid bases with no double bonds are also called 'sphinganines,' those with one double bond are 'sphingenines' (although 'sphingosine' is often used for d18:1 by tradition), and those with two double bonds are sphingediene; (c) if the double bond position is not specified, it is assumed to be between carbons 4 and 5 and *trans* (E), as shown. The stereochemical relationship between the 2-amino and 3-hydroxy-groups are as shown (termed 'D-erythro-' or '2 S,3 R' for sphingosine), although some organisms have sphingoid bases that deviate from this stereochemistry (Pruett *et al.*, 2008).

The fatty acids of ceramides are usually 14–26 carbons in length (and longer for skin), with one or no double bonds and sometimes an α -hydroxyl (and, again, as a special case for skin, an ω -hydroxyl). Although there is often less structural variation in the fatty acids of sphingolipids than for glycerolipids, the number of backbone subspecies can still be considerable when variation in the sphingoid base and fatty acids are both considered. For example, a LIPID MAPS analysis (Quehenberger *et al.*, 2010) of human plasma sphingolipids using liquid chromatography-tandem mass spectrometry (Shaner *et al.*, 2009) found ~100 sphingomyelin subspecies varying in the ceramide backbone due to the presence of several sphingoid bases and amide-linked fatty acids in numerous combinations.

Multiple categories of complex glycosphingolipids are made by addition of carbohydrate headgroups at carbon 1. The major subcategories (highlighted by the first three structures in Figure 3) are: (1) glucosylceramides (GlcCer) and downstream metabolites; (2) galactosylceramides (GalCer) and downstream metabolites; and (c) ceramide phosphoinositols (which are common in plants, fungi, and many other organisms, but not in mammals) that can be further elaborated by additional sugars (such as mannose). Ceramide phosphoinositols are also utilized for formation of the GPI anchor for membrane proteins in some organisms, such as yeast (note that these are often referred to as GPI anchors although the lipid backbone is not a 'phosphatidyl-' group). Small amounts of 'lyso-' glycosphingolipids (i.e., sphingoid bases plus a headgroup but lacking the N-acyl-substituent), such as 'psychosine' (1- β -D-galactosylsphingosine) are occasionally encountered, especially in disease.

After these ceramide monohexoses have been made, additional carbohydrates are added to produce an astonishing variety of complex glycosphingolipids. Indeed, the total number of glycan variants is not known, but in 2007, there were approximately 400 structurally characterized headgroups (174 neutral glycosphingolipids, 190 gangliosides and 24

sulfated glycosphingolipids) (Yu *et al.*, 2007). If one adds compounds that have been subsequently discovered and theoretical compounds (intermediates that are likely to exist between two known compounds in a plausible biosynthetic scheme for the larger compound), the total is probably closer to 600 (Merrill, 2011) (the subspecies can be seen online at SPHINGOMAP). This is a large number, but considerably fewer than Avogadro's number.

The majority of the more complex glycosphingolipids are made from GlcCer, and for mammals have been assigned to five 'root structure' families: globo-, isoglobo-, lacto-, neolacto-, and ganglio-) based on first four carbohydrates (designated I to IV), which are shown in Figure 4. This figure also illustrates a useful shorthand for depiction of the carbohydrates from the Consortium for Functional Glycomics (available online) in which the sugars are designated by color (e.g., Glc vs. Gal as blue vs. yellow circles, respectively) and shape (e.g., Glc as a blue circle but N-acetyl-glucosamine, NAcGlc, as a blue square). The linkage between the sugars is also indicated; for example, β 4 inside the Gal of lactosylceramide implies a β 1 $\rightarrow$ 4 bond between Gal II and Glc I (this is written between the symbols rather than inside them) and the orientation of the symbols also indicates the linkage (note for the symbolic representation of ganglioside GM1 that the substituents on Gal II are linked to positions 3 and 4 in the Lewis diagram (i.e., at ca 7 o'clock and 10 o'clock) are displayed in analogous positions in the symbolic representation).

The functions of glycosphingolipids are too diverse to include in this overview, but the underlying theme, whether a simple monohexose containing compound (Ishibashi *et al.*, 2013) or a complex ganglioside (Schnaar *et al.*, 2014), appears to be that these compounds behave differently in biological membrane (therefore and help form regions with special purposes) and the glycan moieties offer a rich library of structures for interactions with cellular proteins (receptors, transporters, membrane trafficking machinery, etc.), extracellular matrix proteins and proteins on neighboring cells, components of immunoregulation, etc. There is also evidence that some of the glycosphingolipids interact sufficiently strongly with each other that they might fulfill the function of both the ligand and target. Furthermore, some sphingolipids undergo substantial metabolism as part of fulfilling their functions, such as removal of sialic acid or release of the bioactive lipid backbone.

Glycosylated sterols

The glycosylated sterols (also called steryl glycosides) refer to a range of sterols (reflective of the type of organism – cholesterol for mammals and sitosterol, ergosterol, campesterol, stigmasterol, brassicasterol and many others for vascular plants, fungi, algae, and other marine organisms – such as starfish and sponges, and some bacteria) that are glycosylated at the 3 β -hydroxyl group with one or more sugars (glucose, galactose, xylose, arabinose, glucuronic acid, and others – again, depending on the organism) (Grille *et al.*, 2010; Ivanchina *et al.*, 2011). The structural prototype is shown with cholesteryl β -D-glucoside in Figure 5 with an example of a more structurally complex steryl glycoside (Mycaloside G from the Caribbean marine sponge *Mycale laxissima*) (Ebada *et al.*, 2010). Some are also acylated on the glycan.

Figure 4 Representative structures of glycosphingolipids – root structures and nomenclature. The structures for these glycosphingolipids are shown using the shape/color symbols that are conventionally used in the glycobiology field (see text). The symbols are defined in the upper left, and an example is given for ganglioside GM1a which is shown both by an explicit structural diagram and symbols. The upper right shows the root structures for glycosphingolipids using the symbol representation. The bottom of the figure shows other types of GM1, an isomeric form (GM1b) and fucosyl-GM1a.

The functions of sterol glycosides are still being elucidated, but they appear to affect the biophysical properties of cell membranes, confer resistance against stresses such as freezing in plants, play a role in seed development and modulation of host immune functions (Grille *et al.*, 2010; Shimamura, 2012). The presence of cholesterol glucoside in mammalian cells has only been recently appreciated, and is interestingly formed from glucosylceramide as the sugar donor and synthesis is induced by heat shock (Ishibashi *et al.*, 2013).

Glycosylated prenols

Glycosylated prenols are comprised of a polyisoprene (polyterpenoid) alcohol that is attached to a glycan via glycosidic, phosphate or pyrophosphate bonds, as seen in the prototype and examples in Figure 6. Dolichol (eukaryotes and archaea)

and bactoprenol (bacteria) are used in sugar transport across membranes and transfer of carbohydrates to acceptors, with attachment of the carbohydrate to the hydroxyl on the terminal isoprene via a phosphodiester for simple monohexoses (Dol-P-Man and Dol-P-Glc) and a pyrophosphate for the larger oligosaccharide (GlcNAc₂Man₉Glc₃), which is used for N-linked glycoprotein biosynthesis (Welti, 2013). The number of isoprene units varies from 18 to 22 for dolichols and 10 to 12 for bactoprenols, and there are also differences in the degree of unsaturation among different sources. The structural variations are becoming more evident as mass spectrometric methods are facilitating the analysis of these compounds (Garrett *et al.*, 2007; Guan and Eichler, 2011).

The structure shown by glycan symbols in Figure 6, Glc₃Man₉GlcNAc₂-PP-Dol, is used for protein N-glycosylation

Glycosylated sterols

Prototype: cholesteryl β -D-glucoside

Example:

Figure 5 Representative structures of glycosylated sterols. A general prototype for these compounds is shown by cholesteryl β -D-glucoside at the top. An example of an oligosaccharide linked to a sterol is shown by mycaloside G.

in the lumen of the endoplasmic reticulum. This and related compounds in the pathway are often referred to as lipid-linked oligosaccharides (LLO) and have been characterized in considerable detail because defects in the pathway are known to cause disease (Welti, 2013).

An example of a polyisoprenol attached to a carbohydrate via glycosidic linkage is also shown in Figure 6 for a plakopolyprenoside, a compound that has been isolated from a marine sponge, *Plakortis simplex* (Costantino *et al.*, 2000).

Saccharolipids

These are compounds in which fatty acids are linked directly to a sugar backbone, as shown in Figure 7. One of the most widely known saccharolipids is the glucosamine-based saccharolipid 'lipid A' component of lipopolysaccharide (LPS) (Raetz *et al.*, 2009) (Figure 7). They show considerable structural variation among organisms (Banoub *et al.*, 2010) and have complex functions and effects on the GI tract (Rhee, 2014). Another example of a saccharolipid is the acylated trehalose of *Mycobacteria* (Rombouts *et al.*, 2011).

Glycosylated polyketides

These are a structurally diverse group of natural products that are comprised of a 'lipidic' backbone (in the sense that it is relatively soluble in organic solvents and biosynthetically derived from acetyl- or malonyl- units) and a glycan (Hertweck, 2009). The structures of glycosylated polyketides are so diverse that no single figure can encompass all of the members of this subclass, so two examples, avermectin and erythromycin, are shown in Figure 8.

The lipidic portion of polyketides encompasses a wide range of structural features, including polyphenols, macrolides, polyenes, enediynes, and polyethers. The glycosyl groups are

also structurally diverse, but have been suggested to offer an easier handle to 'mine' for new compounds using glygenomics and mass spectrometry (Kersten *et al.*, 2013).

These compounds are produced by a wide range of organisms and include many common antimicrobial, antiparasitic, and anticancer agents, such as the avermectin and erythromycin shown in Figure 8.

Glycosphingolipids – The Power of Combinatorial Biochemistry

The term 'combinatorial' was applied to chemical synthesis when methods were developed to make large numbers of compounds by relatively simple operations. Its aptness for sphingolipid biosynthesis was soon noted (Hannun *et al.*, 2001; Kolter *et al.*, 2002), and continues to be pertinent as more genes and enzymes for glycolipid biosynthesis are found. In essence, then, the idea is that a very large number of glycolipids can be made because there is a large number of enzymes that make the lipid backbones and a large number of glycosyltransferases that can elaborate the headgroups. However, this also limits the number of products that can be made due to the specificities of these enzymes, and because different combinations are expressed in different tissues. Other factors that can affect the types of compounds that are made include subcellular localization of the enzymes and substrates, the presence of binding and transport proteins, etc.

Sphingolipid Backbone Biosynthesis

Sphingolipid biosynthesis *de novo* (Merrill, 2011; Yamaji and Hanada, 2014) begins with the condensation of serine and a

Glycosylated prenols

Prototype: Dolichol-{glycan, phospho-glycan or pyrophospho-glycan}

Examples:

Glc₃Man₉GlcNAc₂-PP-Dolichol

Figure 6 Representative structures of glycosylated prenols. A general prototype for these compounds is shown at the top, with the types of chain lengths for bacterial ($n=6-8$) versus plant and animal ($n=14-18$) shown. The examples include the types of carbohydrates found in the dolichol pyrophosphates used in glycoprotein biosynthesis, with the full oligosaccharide shown in shape/color symbols. The bottom structure demonstrated that other glycans are also found in some organisms.

fatty acyl-CoA (myristoyl-CoA for d16-, palmitoyl-CoA for d18-, and stearoyl-CoA for d20-sphingoid bases) by SPT to produce 3-ketosphinganine with these chain lengths (Figure 9). Thus, this is the first step where the structure of the backbone is defined and is controlled by expression of SPT isoforms or accessory proteins that modify its fatty acyl-CoA selectivity.

The 3-keto-group is rapidly reduced and the product, sphinganine, is also at an important branchpoint (Figure 9) – determination of the nature of the fatty acyl group of the backbone. Sphinganine is N-acylated to dihydroceramides (DHCer) by ceramide synthases (CerS) that control the fatty acyl chain length as shown (e.g., CerS1 adds mainly stearic acid, C18:0, as shown in the highlighted portion of the diagram).

DHCers are also at a key branchpoint because they can be desaturated or hydroxylated to 4-hydroxyDHCer (also referred to as phytoceramides) as shown in this diagram as the lower octagon. Most mammalian tissues have mainly ceramides, but 4-hydroxy-ceramides are common in skin and epithelial tissues. The other option for DHCer (and for ceramides, as shown in this diagram) is for a headgroup to be added to make sphingomyelins (SM), ceramide phosphate (CerP), glucosylceramides (GlcCer), or galactosylceramides (GalCer) (Figures 9 and 10). Small amounts of ceramide phosphoethanolamines are also made by mammals, and these are the major phosphosphingolipid for some organisms (such as fruit flies). Some organisms, such as yeast, also produce ceramide phosphoinositols as their major phosphosphingolipid.

Saccharolipids

Prototype: Fatty acid linked directly to a sugar backbone

Example:

Figure 7 Representative structures of saccharolipids. A general prototype for these compounds is shown at the top, with an example of the Ldo2-Lipid A portion of the lipopolysaccharide of gram-negative bacteria.

Glycosylated polyketides

Examples:

Figure 8 Representative structures of glycosylated polyketides. These compounds are too varied in structure to represent by a general prototype, but two examples are shown in avermectin and erythromycin.

Glycosphingolipid root structure biosynthetic pathways

Figure 10 Glycosphingolipid root structure biosynthetic pathways. This diagram continues the metabolic pathway begun in [Figure 9](#) with the subsequent metabolic steps for the galactosylCer family and the root structure families downstream from lactosylCer. For more information about this pathway, see Merrill, A.H., Jr. 2011. Sphingolipid and glycosphingolipid metabolic pathways in the era of sphingolipidomics. *Chemical Reviews* 111, 6387–6422, from which it was modified.

[Figure 11](#) displays another important concept in thinking about glycosphingolipid biosynthesis: that a single glycosyltransferase might recognize multiple substrates and thereby produce many products ([Kolter et al., 2002](#)). This helps explain how cells can produce many more glycosphingolipids than there are genes that code for glycosyltransferases. Thus, as one examines the gene expression profile for a given system, the possible appearance of downstream metabolites might be manifested in side pathways rather than the one of original focus.

A useful source of information on glycosyltransferases is the series edited by N. Taniguchi *et al.* (eds.), *Handbook of*

Glycosyltransferases and Related Genes, DOI 10.1007/978-4-431-54240-7_33.

Analysis of Glycolipids by ‘Omic’ Technologies

Since no method is available to truly conduct a comprehensive glycolipidomic analysis, studies will actually encompass a subgroup of the glycolipidome that is defined by the investigator’s technical capabilities and/or goal for the analysis. This said, if an investigator is mainly interested in particular glycan

Ganglioside biosynthesis as a 'combinatorial' pathway

Figure 11 Ganglioside biosynthesis as a 'combinatorial' pathway. This diagram continues the metabolic pathway begun in [Figure 10](#), illustrating how glycosyltransferases can act on different substrates that share critical features but differ otherwise; therefore, multiple downstream metabolites can be made from a limited number of glycosyltransferases. For each glycosyltransferase, the added carbohydrate is indicated by a red border. For more information about this pathway, see Merrill, A.H., Jr. 2011. Sphingolipid and glycosphingolipid metabolic pathways in the era of sphingolipidomics. *Chemical Reviews* 111, 6387–6422, from which it was modified.

subspecies, there are methods to profile them using lectins or antibodies ([Cummins and Etzler, 2009](#)). Likewise, mass spectrometry has been used based to profile the glycans released by chemical or enzymatic cleavage followed by matrix-assisted laser desorption/ionization (MALDI) mass spectrometry ([Parry et al., 2007](#)).

Intact glycolipids can be more difficult to analyze. Analysis of glycosphingolipids, as an example, usually requires some form of chromatography for the separation of isomeric species (as reviewed in [Haynes et al., 2009](#)). Nonetheless, in some respects, glycomics mass spectrometry is easier than other approaches for identification of new aglycones for glycolipids ([Wuhrer, 2013](#)).

Perspective on the Future of Glycolipid Research

Glycomics has been revolutionized over the past decade by the development of powerful tools, but glycolipid analysis

remains an especially daunting challenge because it must establish the structures, and quantity, of compounds that are sometimes present in trace amounts and comprised of two difficult-to-analyze components – glycans and lipids. One might argue that many of these compounds are present in relatively small amounts (for example, GlcCer is often only 5 to 10% of the abundance of sphingomyelin); however, cells still contain a lot of glycolipid molecules! For example, RAW264.7 macrophages have an average 53 million molecules of GlcCer/cell, and ca 1 million molecules of the less prevalent GalCer. Furthermore, upon activation of the cells, these numbers increase 2–4 fold ([Sims et al., 2010](#)). Such large increases in amount provocatively suggest that something important is happening. Changes in membrane dynamics? Interactions between glycolipids and membrane proteins?

The large numbers of exogenous glycolipids might also impact us in ways that are only beginning to be appreciated. The microflora that live on and in us produce many bioactive

glycolipids, including a potent immunomodulator, α -galactosylceramide, that was initially found in sponges but has recently been found to be produced by *Bacteroides fragilis* in the human gut microbiota (Wieland Brown *et al.*, 2013). There is undoubtedly much left to learn about glycolipids and how these compounds affect our lives.

Glossary

Anionic lipid A lipid with an overall negative charge at physiological pH; also called an acidic lipid. PtdOH, PIPs, and PtdSer are anionic lipids.

Bioactive lipid A cellular lipid that stimulates or propagates biological signaling pathway(s).

Eicosanoid A signaling molecule produced through oxidation of a 20 carbon fatty acid such as arachidonic acid or eicosapentanoic acid. Leukotrienes, prostaglandins, prostacyclins, and thromboxanes are all eicosanoids.

Endocannabinoid The arachidonic acid-derived neuromodulatory lipids anandamide (AEA) and 2-arachidonoylglycerol (2-AG) present in neurons.

G-protein coupled receptor Seven pass transmembrane receptors that constitute a large superfamily of receptors in eukaryotes. Activation of a GPCR by an agonist stimulates intracellular signaling cascades.

Lipidome The complete set of lipids in a cell or organism.

Lipid raft Membrane microdomains comprised primarily of cholesterol and sphingomyelin that are less fluid than surrounding membrane and serve as organizing centers for protein signaling complexes.

Metabolome The complete set of metabolites in a cell or organism.

Signalsomes A complex of signaling proteins, typically present at the plasma membrane, but known to occur at various membranes throughout the cell to a lesser extent.

Introduction

Lipid signaling refers to the lipid-dependent activation or propagation of a signal within a cell. For example, priming of synaptic vesicles for release from a synapse, splicing of messenger RNAs, and T-cell receptor responses are all dependent on specific lipids to activate, recruit, or regulate proteins involved in the process. Lipids also form the membrane barriers that separate organelles within a cell, and one cell from another. In the form of triglycerides, lipids store energy analogous to the storage of glucose as glycogen, but in a more efficient manner, yielding 2385 kcal mol⁻¹ (palmitate) versus 670 kcal mol⁻¹ (glucose). And, in a method unique to lipids, there is significant interconversion of one lipid type to another by headgroup exchange or modification and by fatty acid exchange or remodeling, leading to a highly dynamic system.

The majority of research identifying and analyzing lipid second messengers have been conducted in cultured cells. This can occasionally result in confusion due to variations in lipid and protein compositions in different cell types. Where possible, information is provided in a general context and signaling pathways that are restricted to a particular cell type are noted.

This article provides an overview of the primary classes of mammalian signaling lipids. Particular emphasis is placed on the regulation of signaling lipids, and the mechanisms by which they participate in signal transduction. Because signaling lipids participate in most signaling pathways and processes, we have not attempted to review their physiological functions. Instead, we recommend several resources at the end of this article.

Lipid Classification and Nomenclature

The Lipid Maps Consortium has developed a classification system for lipids that has become internationally accepted.

Under this system lipids are divided into eight categories, six of which are found in mammals and listed in Table 1. All six categories contain members that play dominant roles in signaling pathways, although the prenol lipids and sterol lipids are not discussed in this review. Prenol lipids are covalently attached to proteins, and exert their effects on signaling by altering the localization of the protein, which is outside the scope of this article. Sterols include a wide range of lipid molecules that have many functions, and contribute to signaling through both structural effects and intracellular receptor binding (see Maxfield and van Meer, 2010; Hulce et al., 2013).

Each lipid category is divided into classes that are distinguished by headgroup and lipid backbone structure. These classes are further separated into subclasses based on additional chemical criteria such as headgroup type, lipid tail organization, and tail linkage (e.g., ester vs. ether linkages). The final organization is similar to the taxonomic rankings of phylum, species, and class hierarchy of the biological Tree of Life, and provides a familiar framework for non-lipid

Table 1 Lipid classification system from the Lipid MAPS Consortium

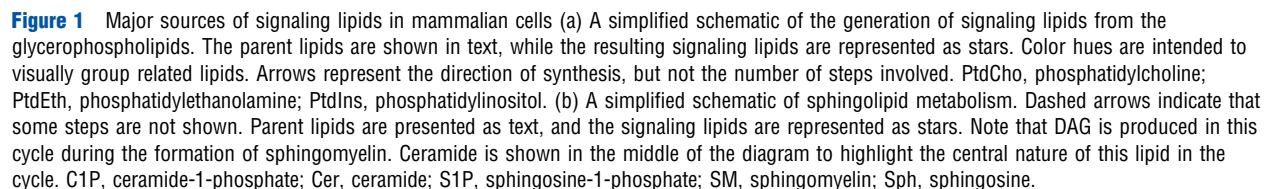

Category	Number of classes	Members discussed in this article
Fatty acyls	14	Arachidonic acid and Eicosinoids
Glycerolipids	6	DAG
Glycerophospholipids	21	PtdOH and phosphoinositides
Sphingolipids	10	S1P
Sterol lipids	6	n/a
Prenol lipids	5	n/a

Note: The above table presents the six categories of lipids present in mammalian cells, as well as the number of classes within each category. For clarity, the subclasses are not listed. The members of each category that are discussed in the text are noted.

Exceptions to this include lysolipids such as lysophosphatidic acid (LPA) and sphingosine-1-phosphate (S1P), and fatty acids such as arachidonic acid and the eicosanoids. Due to their charged state and reduced hydrophobic nature fatty acids are soluble in water to millimolar concentrations and can readily leave membranes.

While there are thousands of species of signaling lipids, the vast majority are the products of two main groups: the glycerophospholipids and the sphingolipids. Additionally, there are two primary metabolic networks that produce the majority of the signaling lipids of the cell: the PI cycle and the sphingolipid cycle. A simplified representation of the metabolic interconversions of the glycerophospholipids to form signaling lipids is presented in [Figure 1\(a\)](#). Because the PI cycle is a central source of signaling lipids, PtdIns is separated from the other phospholipids in the diagram. However, PtdCho is also an important source of signaling PtdOH, and PtdEth has been implicated as a major source of arachidonic acid (the precursor to the major signaling eicosanoids) in some tissues. The arrows represent the typical direction of synthesis, and double arrows are placed where signaling lipids are known to frequently interconvert. The signaling lipids themselves are depicted as stars. It is important to note that while PtdOH is the metabolic precursor for *de novo* synthesis of lipids at the endoplasmic reticulum (ER), this pool of PtdOH contains a distinctly more saturated fatty acid profile and is not utilized in signaling pathways.

The canonical signaling lipids include the phosphatidylinositols (PIs, primarily phosphatidylinositol-4-phosphate, phosphatidylinositol-(4,5)-bisphosphate and phosphatidylinositol (3,4,5)-trisphosphate), diacylglycerol, phosphatidic acid, sphingosine-1-phosphate, ceramide-1-phosphate, and eicosanoids. With the exception of diacylglycerol and the sterols, the major signaling lipids carry one or more negative charges that provide binding specificity and stabilize protein-lipid interaction. These lipids are confined to membranes due to the strongly hydrophobic nature of the fatty acids attached to the lipid backbone, which are below the soluble plane of the membrane. Lipid-binding proteins (LBPs) typically interact with the lipid headgroup and some of the lipid backbone, but rarely have direct interactions with the fatty acid chains. The bound lipid does not leave the membrane, but rather acts as a temporary tether to retain an effector protein at the interface.

a sphingoid base as the backbone rather than a glycerol moiety, and are metabolically and chemically distinct from the glycerophospholipids. An abbreviated representation of the sphingolipid pathway is shown in [Figure 1\(b\)](#). Note that ceramide is the central lipid in the sphingolipid cycle and the source from which the other sphingolipids are derived. There is significant interconversion between ceramide and the other pathway constituents (represented by double arrows), however C1P and S1P are the most well-studied signaling molecules in this group. While there is a wealth of experimental data showing that ceramide and sphingomyelin contribute to the formation of lipid domains (aka lipid rafts) which promote the clustering of signaling proteins into signalsomes, signaling through rafts is not discussed in this article because the lipid effect is general and does not involve specific partner interactions. Note that diacylglycerol (DAG) is produced in the sphingolipid cycle during the formation of sphingomyelin. It is important to remember that these pools of DAG are often spatially distinct from DAG derived from the PI cycle, and contain fatty acid species that are more saturated than those derived from PI(4,5)P₂, which may influence their signaling properties.

Signaling Lipids are Spatially Restricted and Scarce

Tight regulation of signaling lipids is reflected in their low abundance, even in tissues that specialize in processes that depend on bioactive lipids. For example, phospholipids represent approximately 65% of total cellular lipids, but the combined pool of phospholipid-derived signaling lipids may represent less than 1% of that value. However, quantitative methods such as mass spectroscopy have revealed general patterns in the relative abundance of many bioactive lipids. For example, DAG and PtdOH are approximately an order of magnitude more abundant than the phosphatidylinositols, with PI(4,5)P₂ and PI(4)P contributing approximately 61% and 37% or the PIPs, respectively ([Guillou et al., 2007](#)). Overall, it has become clear that the location and abundance of signaling lipids is carefully regulated to maintain coherent signaling networks ([Figure 2](#)).

While the temporal and spatial resolution of signaling lipids is still poor due to the high mobility, rapid metabolism, and low abundance of bioactive lipids within a cell, the combined data from fluorescent lipid-binding probes and lipidomic studies of organelles indicate that the distribution of signaling lipids varies throughout the cell. These observed distributions typically correspond with the functional requirements of the cell. For example, trafficking pathways are highly dependent on PtdOH for fusion and budding of vesicles from the Golgi, and PtdOH can be seen concentrated at the Golgi apparatus. Interestingly, individual phosphatidylinositol subclasses are also enriched in various organelles, and control the recruitment of stage-specific proteins to different compartments. For example, PI(4,5)P₂ is highly concentrated in the cytosolic leaflet of the plasma membrane where it participates in the production of second messengers and is instrumental in endocytosis, PI(3)P is associated with early endosomes where it recruits adapter proteins, and PI(4)P is abundant at the Golgi apparatus where it is important for

trafficking ([Di Paolo and De Camilli, 2006](#); [Mayinger, 2012](#)). Cellular partitioning is also evident for other lipids that serve structural roles, which is beyond the scope of this article but is outlined in several excellent reviews ([Bader et al., 2011](#); [Nicolson, 2014](#); [Coskun and Simons, 2011](#)).

Signaling lipids have recently been examined at the mitochondria, leading to several unexpected findings. Approximately 5% of the cellular PI(4,5)P₂ is found at the mitochondrial outer membrane. While this seems like a minor amount, when normalized to the membrane surface area, the resulting density is approximately 25% of that found at the plasma membrane ([Nemoto and De Camilli, 1999](#)). This pool of PIP₂ has been shown to recruit a form of synaptojanin 2, a phosphatidylinositol phosphatase important for uncoating vesicles, to mitochondria, and appears to be important for the intracellular localization of mitochondria. The phosphatidylinositol-4-phosphate 5-kinases which generate PI(4,5)P₂ and a form of PLD that produces the substrate lipid for PIP₂ production have also been identified at the mitochondrial membrane, indicating a separate PIP₂ signaling network at this organelle. Subsequent studies have shown this network regulates fusion, fission, and localization of mitochondria in cells ([Huang and Frohman, 2009](#)).

Another important finding resulting from combined research efforts is the identification of independent lipid signaling pathways within the nuclear matrix. This finding was controversial for many years due to lack of evidence for any membranous structures in the nuclear matrix. However, independent laboratories identified all the necessary components for a nuclear PI cycle, as well as nuclear lipid effectors such as the Star-PAP polyA polymerase ([Li et al., 2013](#)), PIP₂-activated splicing factors, and nuclear DAG-binding proteins such as PKC α . PI(4,5)P₂ has been detected *in situ* using antibodies ([Tabellini et al., 2003](#)), and lipid microdomains ([Cascianelli et al., 2008](#)) and lipid droplets ([Layerenza et al., 2013](#)) have been detected in the nucleus. The combined evidence has resulted in the general acceptance of a separate lipid signaling web in the nucleus of cells.

The Complexity of Lipid Signaling

Bioactive lipids participate in a vast number of signaling pathways from proliferative to apoptotic, throughout development and aging, in metabolic, catabolic, trafficking, and regulatory processes. This diversity arises from the wide array of interacting protein partners, the integration of multiple, simultaneously active signaling pathways, and the substantial diversity inherent within the lipid molecules themselves. The Lipid MAPS Consortium currently lists over 28 000 individual lipids in the categories covered in this article, encompassing variations in lipid class, headgroup, fatty acid linkage, and fatty acid composition such as elements of unsaturation and a variety of lipid chain modifications. The purpose(s) of the extraordinary diversity within the lipid complement remains enigmatic. Not all will be relevant to signaling, but there are likely to be additional as yet unidentified patterns responsible for variations in signaling responses.

Phosphatidylinositol lipids provide a significant amount of diversity on their own. Variations in phosphorylation patterns

Figure 2 Spatial organization of signaling lipids. The subcellular locations of the major signaling lipids are represented in a stylized schematic of a mammalian cell. Note that all signaling lipids are present at the inner plasma membrane, but are not present at the outer plasma membrane. The most abundant phosphatidylinositols (by mass) have darker shading than the less abundant members. Remodeling of PIPs results in enriched populations that are reliable markers for the various vesicle subtypes as they proceed through the endocytic cycle or split off into recycling endosomes (indicated by arrows). Although DAG and PtdOH are abundant at the ER (the main site of phospholipid synthesis), these pools do not appear to be involved in signaling reactions and therefore are not represented in the diagram. DAG, diacylglycerol; ER, endoplasmic reticulum; MVB, multivesicular body; PtdOH, phosphatidic acid.

on the inositol ring produce seven species of phosphatidylinositols, which are recognized by a variety of lipid-binding domains in proteins. PIP₂ represents a special class of signaling lipid since it is also a precursor for diacylglycerol and phosphatidic acid for

second messenger signaling, and for the synthesis and release of endocannabinoids from arachidonic acid.

At a general level, lipid signaling can be separated into two basic categories: first messenger signaling, in which a bioactive

lipid binds to and activates a receptor at the cell surface, and second messenger signaling, in which a bioactive lipid produced in response to receptor stimulation triggers downstream signaling cascade(s).

Extracellular Signaling Lipids Interact with Receptors

A number of signaling lipids are released from cells and initiate signaling pathways by stimulating extracellular receptors. These lipid ligands include sphingosine-1-phosphate, lysophospholipids (primarily platelet activating factor and lysophosphatidic acid), and members of the arachidonate-derived eicosanoid family (prostaglandin, leukotriene, thromboxane, and the neuronal cannabinoids). These relatively water-soluble lipids are produced by enzyme-mediated hydrolysis of membrane-associated parent lipids and released into the extracellular space where they associate with cognate receptors on the same or nearby cells. With few exceptions, extracellular lipid receptors belong to the G-protein coupled receptor (GPCR) superfamily, and downstream events are defined by the individual receptor dynamics. One notable exception is the apparent stimulation of inflammatory toll-like receptors (TLRs) by long chain fatty acids such as palmitate, suggesting a potential contribution of free fatty acid levels to symptoms of type 2 diabetes (Mamedova *et al.*, 2013).

Intracellular Signaling Lipids Interact with Proteins

Second messenger lipids are produced as a direct or indirect consequence of the stimulation of a vast array of extracellular receptors. The archetypal example of lipid signaling is the PI-PLC-mediated cleavage of PI(4,5)P₂ to produce IP₃ (which increases intracellular calcium) and the bioactive lipid DAG – a strong activator of PKC (and other) enzymes. The most

common mechanism of lipid-induced protein activation is through interaction of the lipid headgroup with a structural motif on the effector protein often referred to as the lipid-binding domain (LBD). The lipid-binding protein is also referred to as an effector protein because it propagates the signal initiated at the membrane receptor.

LBD – Lipid interactions typically involve the lipid headgroup, backbone, and one or more of the fatty acid moieties, but can also include some of the fatty acid chain itself. Fatty acid binding may indeed be a driving factor in ceramide and C1P associations with their protein partners. However, it is more common that the fatty acid physiochemistry facilitates binding indirectly by altering the lipid headgroup positioning within the membrane, or by promoting the formation of lipid domains that regionally concentrate protein partners and/or alter membrane properties (Lipowsky, 2002; Bigay and Antonny, 2012).

Proteomics studies have identified thousands of LBD-containing proteins in organisms from bacteria through primates. By rough calculation, approximately 6–8% (Based on the assumption that there are 20 000 protein-coding genes in the human genome, and using reported numbers of lipid-binding proteins published by the Lipid MAPs Consortium or by manual summation of LBDs extracted from the EBI InterPro database.) of the protein-coding genes in the human genome contain one or more LBDs, and the majority of these have reported signaling functions (Hunter *et al.*, 2012). This is likely to be an underestimate based on the observation that some LBDs, such as those that bind PtdOH, ceramide, and C1P, do not contain a readily identifiable lipid-binding motif, but may rely on more general biophysical characteristic(s) of the folded protein for lipid recognition. LBDs identified in proteins using InterPro are shown in Table 2, along with the number of human proteins predicted to contain each one. Note that some proteins contain more than one type of LBD and may be

Table 2 Lipid-binding domains (LBDs) in the human genome

Bioactive lipid	LBD	Number of human proteins containing LBD	InterPro designation
Arachadonic acid-based leukotriene	Leukotriene B4 receptor	8	IPR003981
Arachadonic acid-based thromboxane, prostaglandin	Prostanoid receptors	33	IPR008365
DAG	C1	279	IPR002219 (PKC-like)
PI(3)P	FYVE	78	IPR000306
PI(3,4)P ₂ , PI(4,5)P ₂ , PI(3,4,5)P ₃ (possibly PI(3)P and PI(4)P)	PH	1020	IPR001849
PI(4,5)P ₂ , PI(3,4,5)P ₃	ENTH	55	IPR013809
PI(4,5)P ₂	ANTH	26	IPR011417
PIPs (various)	PX	53	IPR000270
Anionic lipids (PtdSer, PI(4,5)P ₂ PtdOH) in membranes of high curvature	BAR	71	IPR004148
Anionic lipids (PtdSer, PI(4,5)P ₂ , calcium-dependent binding	C2	48	IPR002420 (PI3KC-like)
PtdOH	Unidentified proposed polybasic motifs in proteins	47 Unknown	IPR014020 (PKC- and tensin-like) n/a
Steroids	Nuclear hormone receptor	261	IPR001723
S1P	EDG receptors	8	IPR004061

Note: The designations of the common LBDs are listed, along with the number of proteins that contain the domain as noted in the EBI InterPro database. Proteins may contain more than one lipid-binding domain and therefore may be represented in multiple categories.

represented multiple times in this table. The abundance of phosphatidylinositol binding proteins is conspicuous, underscoring the dominance of the phosphatidylinositols as second messenger lipid signals. Indeed, the PH domain category can be subdivided based on empirically determined specificities for various phosphoinositide headgroups. For example, the PH domain in Akt binds PI(3,4)P₂ and PI(3,4,5)P₃ (see Rong *et al.*, 2001), while the PH domain of phospholipase C δ binds PI(4,5)P₂ (Garcia *et al.*, 1995).

However, this specificity is not always evident in the primary sequence of a protein, which limits *in silico* detection of lipid-binding domains. This has resulted in a stumbling block in the characterization of lipid-signaling networks since empirical methods for detecting lipid-binding domains are often laborious and expensive. In fact, several lipids appear to interact with proteins primarily through nonspecific electrostatic effects. This is the suggested mechanism for signaling through PtdOH and C1P, which are presumed to bind to proteins via a positively charged patch on the protein's three-dimensional structure.

Physiologic Roles of Signaling Lipids

Bioactive lipids are involved in signaling in every cell of every organism – it is difficult to imagine a process or pathway that does not use them. They are particularly prominent signaling molecules in the immune system where various bioactive lipids are required for proper functioning of both the innate and adaptive immune system, in the vesicle traffic required to deliver many proteins to the appropriate organelles and to maintain structure and order within the cell. In addition, metabolic pathways are highly dependent on lipid signals, particularly PIP₃, as are pathways that are dependent on endocytosis and exocytosis, a basic function of all cells, and a specialized function of endocrine cells and neurons.

Signaling Lipids and Disease

Despite their ubiquitous presence, it is rare that a signaling lipid is diagnosed as a causative agent in disease. Rather the protein(s) involved in the regulation of or response to the lipid are regarded as the causative factor. This is due in part to the fact that signaling lipids are much less plentiful and more quickly metabolized than proteins (and therefore much more difficult to detect), and in part to the technological difficulties in analyzing the very hydrophobic lipid molecules. Fortunately, breakthroughs in mass spectroscopic techniques now permit the reliable detection of many lipid species, resulting in the establishment of two relatively new fields: metabolomics and lipidomics. While lipidomic studies directly examine the lipid complements of cells, metabolomics provides complementary information on small molecule metabolites, acting as a reporter of the state of lipid metabolism.

Studies of lipid populations in disease states are providing new insights into lipid function based on lipid–protein mapping efforts. Some of the more prominent findings include roles of lipids in cancer, diabetes, and lipid storage disease (Shevchenko and Simons, 2010), the identification of

endocannabinoids as feedback regulators of synaptic transmission (D'Addario *et al.*, 2013), and the role of saturated free fatty acids as instigators of systemic inflammation in metabolic syndrome (Wymann and Schneider, 2008). In addition, comparative studies have revealed lipid dysregulation in neuronal pathologies including Alzheimer's disease, Parkinson's disease, and bipolar disorder (Touboul and Gaudin, 2014; Rittiner *et al.*, 2014).

Recent Advances in Signaling Lipid Technologies

The study of lipids as signaling entities began in the 1950s with the discovery of the 'PI effect' (Hokin, 1985). Recent advances in mass spectroscopy have made this powerful tool accessible for lipid analysis, ushering in the lipidomics area. Lipidomics is the study of the lipid population, or lipidome, of a tissue, cell or organelle, including the identity of the fatty acid species associated with each lipid. This type of analysis provides detailed information about the changes in cellular lipids resulting from an event of interest, such as the stimulation of a cell by an agonist, or the invasion of a cell by a virus. By following changes in lipid profiles, particularly those of signaling lipids, important information can be gained about the signaling networks that are engaged. This is exemplified in the recent construction of a protein–lipid interactome in the yeast *Saccharomyces cerevisiae* (Gallego *et al.*, 2010).

Additional tools that have become commonplace are the use of fluorescently labeled lipids for evaluating macroscopic lipid organization such as lipid domains and lipid rafts, as well as lipid biosensors, which are modified lipid-binding domains containing an optogenetic tag (often GFP) to allow *in vivo* imaging of specific signaling lipids, particularly the phosphoinositides and diacylglycerol, at the cellular and subcellular level (Gao and Zheng, 2013; Smith *et al.*, 2009; Takatori *et al.*, 2014). These tools provide information on the relative strength, location and duration of lipid signals in response to various stimuli.

As advances in the detection and interpretation of the signaling roles in bioactive lipids progress, so, too, will our understanding of their roles in signaling and disease.

Origins

Making a membrane was an essential step in life appearance allowing chemical reactions to occur in a confined environment. Experiments aimed at defining minimal membrane systems capable of self-generation by division suggest that very simple lipid species are endowed with such properties ([Budin and Szostak, 2011](#)). According to these studies, primitive membranes would have self-assembled from simple single-chain lipids like fatty acids ([Figure 1](#)). Such membranes are loosely

packed, highly permeable to small metabolites, constantly exchange their components with the environment, and can spontaneously divide. Thereafter, the ability to synthesize double-chain lipids would have gradually reduced the probability of lipid loss, making membranes less dependent on the supply of molecules from the environment. However, this increase in membrane stability correlates with a decrease in permeability and a reduced ability to undergo spontaneous morphological changes. Therefore, the transition from single-chain lipids to double-chain lipids might have coevolved with the acquisition

Primitive membrane

Modern cell membrane

Figure 1 From primitive to modern cell membranes. Primitive cellular membranes might have formed from the self-assembly of simple molecules containing one hydrocarbon acyl chain. These membranes are highly permeable and their stability requires continuous exchange with the environment. The ability to synthesize diacyl lipid was probably a turning point to make membranes more stable and therefore less dependent on the environment. In turn, this transition would have required the emergence of intracellular mechanisms to control exchanges across the bilayer and to promote membrane division. Modern cell membranes are extremely complex. They are very rich in transmembrane and peripheral proteins, they contain hundreds of different lipid species, and their two leaflets can be very different in composition. The composition of both bulk and rare lipids is also different between cellular organelles.

of primitive mechanisms to shape membranes and transport molecules across them (Budin and Szostak, 2011).

General Traits of Biological Membranes

In currently living organisms, cellular membranes are extremely complex in composition, using a repertoire of hundreds if not thousands of lipid species (Figure 1). One of the most detailed pictures of a real biological membrane comes from studies of synaptic vesicles, which encapsulate neurotransmitters and are at the basis of communication between neurons (Takamori *et al.*, 2006). Comprehensive lipid and protein analysis (i.e., proteomic and lipidomic studies) reveal a very crowded membrane with numerous proteins of different structure and function and about 50 different lipid species. This complexity is intimidating and raises a central question: Do all details matter or can we extract some general traits that distinguish or unify membrane-bound organelles?

The abundance of transmembrane proteins in the synaptic vesicle is not unique. Although the bilayer structure is governed by the amphiphilic properties of lipids, biological membranes generally contain high amounts of proteins (Engelman, 2005); some of them cross the bilayers through transmembrane helical segments; others are peripherally associated through various means. This crowding probably influences the ability of proteins to move laterally (diffusion), modifies the mechanical properties of membranes, and can lead to membrane heterogeneities.

The building blocks of cellular membranes are glycerophospholipids, sphingolipids, and sterols (Holthuis and Levine, 2005). Glycerophospholipids encompass both bulk lipids, i.e., abundant lipids that allow the membrane to be a bilayer, and rare lipids, which act as second messengers or as a flag of subcellular compartments (Di Paolo and De Camilli, 2006). $PI_{(3,4,5)}P_3$, a phosphoinositide with three phosphate groups on its polar head, is an example of a lipid messenger, acting as a compass for cell polarity (Servant *et al.*, 2000). $PI_{(3)}P$, with one phosphate group on its polar head group is an example of a flag lipid, being present exclusively on some organelles (endosomes) (Burd and Emr, 1998). The most abundant phospholipids are phosphatidylcholine (PC), phosphatidylethanolamine (PE), and phosphatidylserine (PS). PC and PE are zwitterionic since their polar heads contain one negative and one positive charge, whereas PS is anionic since its polar head contains two negative charges and one positive charge (Holthuis and Levine, 2005).

Sphingolipids are deceptively similar to phospholipids as they also contain two acyl chains and one polar head group. However, subtle difference in the chemistry of sphingolipids compared to glycerophospholipids (longer acyl chains and more possibilities of hydrogen bonds) and the fact that complex sugar groups decorate the polar head make their physicochemical properties different. Sphingolipids are abundant on the external face of the cell plasma membrane and play essential roles in cell protection and cell–cell communication (Holthuis and Levine, 2005; Simons and Sampaio, 2011).

Sterols are very different from both sphingolipids and phospholipids being made by a rigid carbon ring structure decorated, on the one hand, by a minimal polar group

(a hydroxyl group) and, on the other hand, by a short carbon chain. A high concentration of cholesterol helps membranes to be impermeable to small molecules including water. However, the effects of cholesterol are complex and depend on the nature of the neighboring lipids.

Overall, the identity of each membrane-bound organelle results from the presence of unique proteins and of rare lipids, from the relative amounts of bulk lipids, and from some physical features such as shape or interaction with a protein matrix (e.g., the actin cytoskeleton underneath the plasma membrane). In the case of synaptic vesicles that we have used before as an example, their noticeable features are the presence of key proteins involved in neurotransmitter uptake and release, the abundance of polyunsaturated phospholipids and cholesterol (40 mol% of all lipids), their extreme curvature (radius 20 nm), and their embedding in a dense protein matrix (Takamori *et al.*, 2006). Endocytic vesicles are also very dynamic organelles whose formation and consumption correlate with abrupt changes in specific phosphoinositides species (Posor *et al.*, 2013).

Most organelles exchange vesicles or other membrane-bound intermediates, a process referred as to membrane traffic. Consequently, the physicochemical features of many organelles vary according to their position along major trafficking routes. Thus, the endoplasmic reticulum (ER) and the plasma membrane define two extreme cases in term of lipid composition, whereas organelles such as the Golgi apparatus or endosomes display intermediate traits. In this respect, two parameters define a first layer of organelle identity: membrane electrostatics, which depends on the abundance of negatively charged lipids (PS and phosphoinositides); and lipid packing, which depends on the presence of ‘kinks’ in fatty acid chains and on cholesterol levels (Bigay and Antonny, 2012; Holthuis and Levine, 2005).

Membrane Electrostatics

The gene product Src has a central history in cancer biology, as it was the first proto-oncogene to be discovered. In addition, illuminating experiments on the membrane targeting of this tyrosine kinase had been instrumental for our understanding of the organelle distribution of many cytosolic proteins (McLaughlin and Aderem, 1995). Src is attached to the cytosolic leaflet of the plasma membrane through an N-terminal sequence, which led to the hypothesis that a membrane protein recognizes this sequence. Because experiments aimed at identifying this putative Src receptor failed, another hypothesis emerged: the N-terminal sequence of Src, which is very rich in positively charged residues, interacts directly with negatively charged lipids. This second hypothesis turned out to be true: the membrane targeting of Src, both *in vitro* and *in vivo*, as well as its transforming activity correlate with the density of positively charged residues in the N-terminus, regardless of its exact amino acid sequence (McLaughlin and Aderem, 1995).

As rudimentary as it may seem, membrane electrostatics is a powerful mean to target cytosolic proteins to the plasma membrane. The cytosolic leaflet of this membrane is indeed very rich in negatively charged lipids, notably PS (net charge = -1) and $PI_{(4,5)}P_2$ (net charge = -4), as compared to

other organelles. Thus, artificial constructs bearing 2, 4, 6, or 8 accessible positively charged residues show a gradual enrichment at the plasma membrane at the expense of internal organelles (Yeung *et al.*, 2006). In many cases, close variants of the same protein (e.g., small G proteins of the Ras or Rho subfamilies) are targeted to different organelles owing to differences in the number of positively charged residues of their membrane targeting sequence.

Nonspecific electrostatic interactions between peripheral proteins and membranes are quite weak. Consequently, they generally combine with other elementary mechanisms of membrane anchorage. In the case of Src, a myristate (a 14-carbon acyl chain) is covalently attached to a glycine upstream of the N-terminal-basic sequence. Strong binding of Src to the membrane results both from myristate insertion in the hydrophobic core of the membrane and from electrostatics interactions of the N-terminal sequence with the membrane surface (McLaughlin and Aderem, 1995). The combination of weak interactions is a recurrent theme in membrane targeting mechanisms and has two advantages. First, it allows cycles of membrane association-dissociation because disrupting one elementary membrane interaction (e.g., phosphorylation of a basic sequence) is generally sufficient to promote protein detachment. Second, it improves the specificity of membrane targeting: binding occurs only when the membrane displays features that are compatible with the association of each elementary membrane-anchoring motif (e.g., negatively charged lipids and curvature).

Overall, membrane electrostatics governs a membrane territory that starts at the *trans* Golgi, includes various endosomal membranes and culminates at the plasma membrane. Not surprisingly, protein machineries that work in or on these membranes take advantage of this feature. A good example is cortical actin, whose nucleators at the plasma membrane interact with the phosphoinositide PI(4,5)P₂ and PS (Papayannopoulos *et al.*, 2005).

Lipid Packing

The majority of lipids that form biological membranes have a cylindrical shape: their polar heads have approximately the same cross-sectional area as their acyl chains. The best example of a cylindrical lipid is C16:0-C18:1 PC, which contains one saturated (C16:0) and one monounsaturated acyl chain (C18:1). This balance in molecular size allows the formation of stable bilayers (Holthuis and Levine, 2005). Yet, biological membranes also contain lipids whose shape would result in assemblies different from bilayers if those components were the majority. Consequently, most biological bilayers are under stress: the packing of their lipid components is not perfect and probably results in the formation of voids or 'defects' (Bigay and Antonny, 2012).

Although somehow counterintuitive, the presence of lipid packing defects in biological membranes is functionally important. First, lipids with a non-bilayer shape facilitate complex reactions such as membrane fusion, in which the membrane transiently and locally loses its bilayer structure (Zick *et al.*, 2014). Second, the propensity of cellular membranes to be loosely or tightly packed seems correlated with

their functions. The ER contains low levels of cholesterol and its glycerolphospholipids are generally monounsaturated: their acyl chains contain a *cis* double bond (e.g., C18:1), which creates a kink right in the middle of the hydrocarbon chain. In contrast, the plasma membrane is rich in cholesterol and in saturated lipids (Schneider *et al.*, 1999). Lipid homeostasis pathways help to maintain these parameters within narrow ranges. For example, transmembrane proteins of the ER sense the level of cholesterol and trigger a feedback loop response that ultimately controls sterol synthesis (Radhakrishnan *et al.*, 2008).

The loosely packed structure of the ER membrane probably facilitates protein and lipid synthesis reactions that occur in the hydrophobic matrix (Bretscher and Munro, 1993; Deguil *et al.*, 2011; Nilsson *et al.*, 2001). Conversely, tight packing between cholesterol and saturated (straight) acyl chains at the plasma membrane is important for making this membrane an efficient cell barrier. In specialized cells, other adaptations of the hydrophobic matrix have been reported. The discs of photoreceptor discs are made almost exclusively of polyunsaturated PLs. These highly flexible lipids facilitate the conformational change of rhodopsin, thereby contributing to the exceptional signal to noise ratio of phototransduction (Mitchell *et al.*, 2001). More recently, a gradient of polyunsaturated phospholipids has been reported along the axon (Yang *et al.*, 2012). The function of this gradient is not known but it is probably related to the extraordinary enrichment of polyunsaturated PLs in synaptic vesicles (Takamori *et al.*, 2006). *In vitro*, polyunsaturated PLs facilitate membrane deformation and fission (Pinot *et al.*, 2014).

In conclusion, the membrane territory governed by lipid packing roughly mirrors that defined by electrostatics: membranes of the early secretory pathway (ER to *cis* Golgi) seem to combine loose lipid packing and low electrostatic, whereas membranes of the late secretory pathway (*trans* Golgi, endosomes, and plasma membrane) seem to combine tight lipid packing and high electrostatics (Figure 2).

Membrane Subdomains

In a closed membrane, the general tendency of proteins and lipids is to diffuse within the full membrane area to maximize entropy. Typically, a lipid explores the entire surface of the plasma membrane in a few minutes. Yet, biological membranes are not uniform. The plasma membrane of epithelial cell is divided into a basolateral region and a highly protective apical membrane barrier (Simons and van Meer, 1988). When the yeast *Saccharomyces cerevisiae* divides, the continuity of the ER is interrupted to prevent the daughter cell from acquiring 'aging factors' that have accumulated on the ER membrane of the mother cell (Clay *et al.*, 2014). At the *trans* Golgi network or in endosomes, membrane domains form to prepare the emergence of different types of transport intermediates (Sonnichsen *et al.*, 2000).

A complex issue in membrane biology is to determine what factors govern the emergence of membrane subdomains. A popular but controversial hypothesis is that these domains arise from the tendency of some lipid species to form different phases; classically a liquid ordered phase rich in saturated

Figure 2 Two membrane territories. The ER and *cis* Golgi membranes are poor in negatively charged lipids and display lipid packing defects owing to the presence of lipids with monounsaturated chains. Membranes from the *trans* Golgi to the plasma membrane harbor negatively charged lipids on their cytosolic face and are tightly packed as they are rich in cholesterol and saturated lipids. These opposite changes in packing and electrostatics are controlled by enzymatic activities, notably at the Golgi apparatus: flippases move phosphatidylserine from the luminal leaflet to the cytoplasmic leaflet (lipid flip-flop). Phospholipases and acyltransferases promote the replacement of the second acyl chain of many phospholipids (lipid remodeling). In addition, membrane contact sites are privileged zones where lipids are exchanged between the ER and compartments such as the *trans* Golgi, endosomes, the plasma membrane, or mitochondria.

sphingolipids and cholesterol and a liquid disordered phase with less saturated lipids (Simons and Sampaio, 2011). However, if such domains can readily form in artificial lipid membranes, their existence in biological organelles remains elusive owing to the difficulty in isolating them (Munro, 2003). Moreover, the bulk lipid composition of most organelles does not seem favorable for the formation of large liquid ordered domains, a notable exception being the outer leaflet of the plasma membrane. Notwithstanding, many other factors might also contribute to the formation of lateral membrane inhomogeneities, including interactions with the underneath cytoskeleton, assemblies of large protein oligomers such as

septins, and numerous other lipid-protein interactions. Overall, if membrane subdomains clearly exist, our understanding of the factors that drive their formation remains fragmental.

Mechanisms that Modifies the Bulk Lipid Composition of Organelles

Several mechanisms contribute to the nonrandom distribution of negatively charged lipids in the cell. First PI-kinases and PI-phosphatases are localized to well-defined organelles

(Di Paolo and De Camilli, 2006). Second, PS is synthesized at the ER but is mostly present on the luminal side of this organelle and as such is inaccessible to cytosolic proteins (Fairn *et al.*, 2011). At the Golgi, transmembrane ATPases or 'flippases' promote the flip-flop of PS from the luminal to the cytosolic leaflet (Zhou and Graham, 2009), thereby making it available for the targeting of cytosolic proteins containing positively charged sequences.

How the cell gradually remodels the acyl chains of its glycerophospholipids, a process referred as to the Land's cycle, has remained mysterious for decades. Lipid remodeling involves the sequential action of phospholipases and acyltransferases to replace the esterified acyl chains on the phospholipid glycerol backbone; for example, to convert a C18:1-C18:1 into a C16:0-C18:1 lipid. The recent cloning of many acyltransferases and the realization that some members reside at the Golgi suggest that this organelle is a privileged region for changing the hydrophobic matrix properties (Shindou *et al.*, 2009).

The activities of lipid flippases, acyltransferases, and other lipid-modifying enzymes likely contribute to the large changes in membrane electrostatics, lipid packing, membrane asymmetry, and membrane thickness that occur at the Golgi, which defines the frontier of two main membrane territories (pre- and post-Golgi membranes). Of note, this frontier also acts as a filter to sort membrane proteins according to the physicochemical properties of their transmembrane domains (Sharpe *et al.*, 2010).

Other mechanisms are being disclosed that maintain different lipid compositions between organelles. Cytosolic lipid transfer proteins extract one lipid from a donor membrane, convey it in the cytosol, and then deliver it to an acceptor membrane. Thus, ceramide transport protein extracts ceramide from the ER and delivers it at the Golgi where ceramide is then transformed into sphingolipids (Hanada *et al.*, 2003). Whether such lipid transfer activities are fast and specific enough to explain the distribution of some lipid species is a long-standing question. Recent studies suggest that two mechanisms might improve the efficiency of lipid transfer reactions (Kim *et al.*, 2013; Mesmin *et al.*, 2013). First, some lipid transfer proteins are equipped with domains that bridge two membranes, leading to the formation of contact sites. Membrane contact sites allow the connection of almost any organelle to the ER, where most lipid building blocks are synthesized, and have a typical width of few tens of nanometers. Within this short distance, many lipid transfer reactions might occur in a coordinated manner. Second, some lipid transfer reactions are coupled: the same protein can transfer one lipid in one direction and another lipid in the opposite direction. As such, phosphoinositide gradients might provide the energy for the fast transfer of lipids such as cholesterol of vitamin E (de Saint-Jean *et al.*, 2011; Kim *et al.*, 2013; Kono *et al.*, 2013; Mesmin *et al.*, 2013).

Membrane Curvature

Pure lipid bilayers are poorly extensible as their area can extend by about 5% before rupture. Because the surface of the plasma membrane is much larger than what would be

required to encapsulate the cell, the cell responds to stretching through other mechanisms such as rupture of plasma membrane-cytoskeleton interactions or takes advantage small invaginations, the caveolae, which act as surface reservoirs (Raucher *et al.*, 2000; Sinha *et al.*, 2011). In contrast, lipid bilayers can be highly bent (Rawicz *et al.*, 2000). In the cell, membrane bending results from the actions of numerous protein machineries (McMahon and Gallop, 2005). The synaptic vesicle (radius 20 nm) is an example of a highly curved membrane that is formed by specialized membrane bending proteins.

The most complex organelle in term of morphology is the ER, which forms a continuous membrane network that emerges from the nuclear envelope and spreads throughout the entire cytoplasm. Many types of membrane geometries are met in this compartment (Shibata *et al.*, 2009). This includes not only long tubules and membrane sheets, but also small spherical vesicles, which transport cargoes toward the Golgi, nuclear pores with a torus-like shape, through which exchanges between the cytosol and the nucleus occur, and flat membrane contact sites with the plasma membrane.

The reticulons and the DP1/Yop1p proteins are transmembrane proteins that contribute to the formation of ER tubules and sheets (Figure 3(a)). These proteins display hairpin-like transmembrane segments that are not long enough to completely cross the bilayer. These hairpins are believed to occupy more volume in the cytosolic leaflet of the ER than its luminal leaflet, thereby leading to membrane deformation. Membrane curvature induced by asymmetric protein insertions in the bilayer matrix is referred as to the wedge mechanism.

The protein machineries involved in vesicle budding from the ER and in nuclear pore formation, the COPII coat and the nuclear pore complex (NPC), respectively, are based on a lattice-like arrangement of cytosolic proteins (Figure 3(b); McMahon and Gallop, 2005). NPC and coat complexes might have derived from the same ancestor (Schwartz, 2013). In both cases, the lattice is intrinsically curved and contacts the membrane indirectly *via* specific adaptors. This mode of membrane deformation where a cytosolic protein or a protein complex imposes its intrinsic shape to the membrane without directly penetrating into the hydrophobic membrane matrix is referred as to the scaffolding mechanism.

The division between scaffolding and wedge mechanisms is instrumental to understand how simple proteins deform membranes (McMahon and Gallop, 2005). However, in many circumstances the wedge and scaffold mechanisms cooperate to shape biological membranes. In the case of reticulon-like proteins, membrane deformation arises not only from the unbalanced chemistry of the hairpin segments but also from the ability of these proteins to oligomerize into arc-like structures. In the case of the COPII coat, the membrane deforming activity of the lattice is assisted by the membrane insertion of amphipathic helices from other proteins (Lee *et al.*, 2005). Amphipathic helices do not cross membrane bilayers but lie at the interface between the polar and nonpolar membrane region. Such shallow mode of membrane insertion is reversible and can be controlled by conformational changes (e.g., the GDP/GTP switch of small G Proteins).

Figure 3 Shaping biological membranes. (a) Membrane deformation by wedges. Reticulon hairpins cross the membrane of the ER in an asymmetric manner, occupying more volume in the cytosolic leaflet than in the luminal one. Amphipathic helices are embedded in the interfacial membrane region, hence causing local deformations. (b) Membrane deformation by scaffolds. Protein coats are typically made of two layers: one contacting directly the membrane and one polymerizing into a spherical scaffold. (c) Atomic models of two amphipathic helices (as viewed from the front). These helices are adapted to different organelles. The helix on the left is an Amphipathic Lipid Packing Sensor: its polar face is made almost exclusively of small and uncharged residues (GLY, SER, THR; in pink), and its hydrophobic face contains bulky hydrophobic residues (LEU, PHE; in yellow). This helix inserts into large lipid packing defects that form in the outer leaflet of small vesicles from the ER or the *cis* Golgi. The helix on the right is the N-terminal region of α -synuclein: its polar face contains two wings of positively charged residues (LYS in blue) and one crest of negatively charged residues (ASP, GLU; in red). Its nonpolar face contains very small hydrophobic residues (VAL, ALA; in yellow). This helix is adapted to vesicles containing negatively charged lipids and small lipid packing defects (e.g., endocytic vesicles arising from the plasma membrane).

As we leave the ER, cross the Golgi apparatus and reach the plasma membrane, we meet other membrane deforming machineries. The most well known are the COPI coat and the clathrin-AP adaptor coats, which share with COPII the same basic architecture: a lattice-like spherical outer layer and an inner layer made of cargo adaptors and amphipathic wedges. However, each coat is adapted to the membrane on which it acts. The COPII coat is attached to the ER *via* the insertion of bulky hydrophobic amino acids of the small G protein Sar1 in the bilayer (Lee *et al.*, 2005), whereas the clathrin coat contacts the plasma membrane *via* adaptors, which recognize the polar head of the phosphoinositide PIP₂ and other anionic

lipids (Jackson *et al.*, 2010). The predominate use of either hydrophobic or electrostatic interactions is also illustrated in Figure 3, which compares the chemistry of two amphipathic helices that adsorb on small vesicles budding from either early membranes (thus characterized by large lipid packing defects) or late membranes (thus containing anionic lipids). This comparison is suggestive of a molecular ‘camouflage’ where each helix is chemically adapted to the membrane interface in which it inserts (Pranke *et al.*, 2011).

Many mechanisms of membrane deformation remain to be analyzed. The entry of some pathogens into the cell is suggestive of primitive modes of membrane deformations that bypass the requirement for specialized cytosolic machineries (Romer *et al.*, 2007). Other interesting examples are the formation of cup-shape membrane structures during autophagy or the deformations induced by endosomal sorting complexes, which occur in the opposite direction as budding by protein coats. Even in the case of protein coats for which spectacular advances have been made, key issues remain; notably how these well-defined protein assemblies cope with extremely crowded membrane surfaces or huge protein cargoes (Copic *et al.*, 2012).

Conclusions

Despite their complexities in composition, the membranes of most cellular organelles can be broadly divided in two groups according to their lipid packing properties and to the presence of negatively charged lipids (Bigay and Antonny, 2012). The ER membrane is poorly packed, a feature probably decisive for its function in protein and in lipid synthesis. The plasma membrane is tightly packed, thus forming an impermeable barrier, and its cytosolic leaflet is very rich in negatively charged lipids allowing the cell to control its shape by using plasma membrane–cytoskeleton interactions. The Golgi apparatus forms the frontier between these two territories and is a privileged place for changes in lipid acyl chain unsaturation, cholesterol content, membrane electrostatics, membrane thickness, and membrane asymmetry.

Lipid Rafts/Membrane Rafts

E London, Stony Brook University, Stony Brook, NY, USA

Introduction

The fluid mosaic model of membrane structure is often thought of in terms of a homogeneous mixture of lipids in a lipid bilayer studded with proteins. An alternative is that there are domains consisting of spatially segregated regions with specialized lipid and protein compositions. Lipid rafts or membrane rafts are the most widely studied of such domains. The name raft was adopted to describe the concept of a specialized small (protein-containing) lipid cluster coexisting with a surrounding ocean of less specialized lipids and proteins. Even though this name has been applied to diverse concepts, for simplicity the name raft will be used here in its most commonly defined sense, physically segregated membrane domains of lipids, generally rich in sphingolipids and sterols, plus associated proteins, existing in the tightly packed liquid ordered (Lo) state. The subject of lipid or membrane rafts has been very controversial. However, recent studies have unequivocally identified raft-type domains in living cells. This article concentrates upon the properties of rafts and how they may be studied.

The Physical States of Lipids in Lipid Bilayers

Phospholipids and sphingolipids can form lipid bilayers in either a tightly packed solid-like (gel) state or loosely packed fluid (liquid disordered, Ld) state. For membrane vesicles composed of a specific lipid, the gel state melts to form the Ld state at a characteristic melting temperature (T_m). As simple physical chemistry predicts, gel and Ld phases often coexist in mixtures of high- T_m value lipids (e.g., natural sphingolipids, which easily form a tightly packed ordered state due to having saturated acyl chains lacking *cis* double bonds) and low- T_m lipids (ordinary phospholipids, which generally have one or more *cis* double bonds in one of their two acyl chains) (Korlach *et al.*, 1999). Since the T_m for sphingolipids is generally at or above physiological temperature, the possibility that natural membranes containing both sphingolipids and phospholipids could contain coexisting solid-like and liquid-like membrane domains was long considered (Thompson and Tillack, 1985). However, large phase-separated membrane domains were not observed in cells. Furthermore, it was thought cholesterol would prevent formation of coexisting solid and liquid domains. When cholesterol is mixed with other membrane lipids, especially lipids containing saturated acyl chains, i.e., lacking double bonds, it was found that a state with intermediate properties forms. This was first named the gamma state, but later called the Lo state (Ipsen *et al.*, 1987; Lentz *et al.*, 1980; Recktenwald and McConnell, 1981; Vist and Davis, 1990). The Lo state is characterized by fast lipid lateral diffusion, as in liquids, but tightly packed and ordered as are solids (London, 2005). It was widely thought that a

homogeneous Lo state might replace separate Ld and gel domains in cholesterol-rich membranes (London, 2002).

Formulation of the Lipid Raft Hypothesis

Interest in membrane domains was revived by studies in both cell and model membranes. Work on cells from van Meer and Simons in 1988 proposed formation of sphingolipid microdomains functioning in sorting of glycosphingolipids and glycosylphosphatidylinositol (GPI)-anchored proteins. It was envisioned that H-bonding induced microdomain formation and GPI-anchored protein association with glycosphingolipids (Simons and van Meer, 1988). It was proposed in another study that detergent resistance might be related to this sorting based on influenza hemagglutinin behavior (Skibbens *et al.*, 1989). The work of Brown and Rose in 1992 provided a breakthrough involving the isolation and characterization of detergent-resistant membranes (DRM) from cells (Brown and Rose, 1992). DRM membrane fractions were rich in sphingolipids, cholesterol, and GPI-anchored proteins, and their detergent resistance provided a potential method to readily isolate membrane domains. (In much earlier studies, a detergent insoluble membrane fraction was isolated from red blood cells by Steck and colleagues, and it was speculated that this might arise from lipid domains, but this study was not widely pursued (Yu *et al.*, 1973).) Brown, London, and colleagues found in 1994 that liposomes composed both of lipids found in DRM and of GPI-anchored proteins exhibited a high degree of sphingolipid, cholesterol, and GPI-anchored protein insolubility in TX-100, as did Lo state liposomes composed of just saturated lipids and cholesterol (Schroeder *et al.*, 1994). It was proposed that DRM arose from Lo-like domains in cells, and that the packing between saturated acyl chains and cholesterol drove both Lo-like domain formation in cells and the association of GPI-anchored proteins (which are anchored in membranes by saturated acyl chains) with such domains (Schroeder *et al.*, 1994). An important report by Ikonen and Simons in 1997 proposed a synthesis of many of the early studies, and popularized the name lipid rafts for cholesterol and sphingolipid-rich membrane domains (Simons and Ikonen, 1997). In addition, studies in 1996 and 1997 detected segregation of lipids into coexisting Ld and Lo domains in ternary mixtures of high- T_m lipid (including sphingomyelin (SM)), low- T_m lipid and cholesterol (Ahmed *et al.*, 1997; Silvius *et al.*, 1996) including that at physiologically relevant compositions of sphingolipid and cholesterol (Ahmed *et al.*, 1997). It was also found that detergent resistance only appeared in mixtures of SM, low- T_m phosphatidylcholine (PC), and cholesterol when SM levels were high enough that Lo domains had formed as defined spectroscopically, confirming Lo domain formation was linked to detergent insolubility (Ahmed *et al.*, 1997). Early reviews in 1997 and 1998 raised many of the issues surrounding domain properties that remain

of interest and concern today (Brown and London, 1997, 1998; Rietveld and Simons, 1998).

What Hold Rafts Together?

The tight packing of lipid molecules in an ordered state bilayer arises from both van der Waals interactions between acyl chains and polar headgroup interactions. Acyl chains with kinks due to *cis* double bonds, especially in the center of the chain, tend to resist tight packing, while long saturated acyl chains favor tight packing. However, a lipid having long saturated acyl chains does not guarantee that it has a strong tendency to form a tightly packed state with neighboring lipids because very large polar headgroups can inhibit tight acyl chain packing due to steric clashes with neighboring lipid headgroups. H-bonding between lipids may also contribute significantly to ordered domain formation (Li *et al.*, 2001; Ramstedt and Slotte, 1999). In this regard, it should be noted that H-bonding groups in the polar headgroup and upper acyl chain region (e.g., alpha OH groups on fatty acids) are in an environment significantly less polar than aqueous solution, and thus may H-bond to each other more strongly than they would in a fully aqueous environment.

Close packing between sterols and other membrane lipids has been detected via the so-called condensing effect of sterols, in which the lateral area taken up by lipids at a given lateral pressure in monolayers is less than additive when sterols are mixed with phospholipid or sphingolipids. Favorable van der Waals interactions are likely to help drive this close packing. In addition, close packing is enhanced by the hydrophobic effect. The small sterol OH group is insufficient to prevent contact of sterol hydrocarbon with water, and close packing allows the sterol to be hidden from water by the larger polar headgroups of neighboring membrane lipids. This is known as the 'umbrella effect' (Huang and Feigenson, 1999). Free ceramide also has a small polar group, and its packing with other sphingolipids is also thought to be partly driven by an umbrella effect (Bjorkqvist *et al.*, 2005; Megha and London, 2004; Zitzer *et al.*, 2001). In fact, when ceramide and sterol are both present in a mixture of high-T_m and low-T_m lipids, competition for sites under polar headgroups of other lipids can lead to displacement of sterols from ordered domains by ceramide (Bjorkqvist *et al.*, 2005; Megha and London, 2004), or a competition that affects binding to proteins (Zitzer *et al.*, 2001). Similar competition reflecting umbrella effects can be observed for several lipid-like molecules with small polar headgroups (Alanko *et al.*, 2005). It should be noted that ceramide-rich ordered membrane domains potentially exist in the gel state. Studies in yeast suggest gel-state domains can sometimes exist in cells (Aresta-Branco *et al.*, 2011).

The basis of raft formation in the cytosolic ('inner') lipid leaflet/monolayer of membranes is unclear. Membrane lipid asymmetry is such that there is little sphingolipid in the cytosolic leaflet of eukaryotic cell membranes. Furthermore, model membrane studies on vesicles roughly mimicking either the exofacial (outer) or cytosolic leaflets of plasma membranes suggest that the lipid composition of the outer leaflet supports spontaneous Lo domain formation while that of the inner leaflet does not (Silvius, 2003; Wang and Silvius, 2001).

Nevertheless, numerous lipid-anchored cytosolic peripheral proteins appear to be raft-associated (Melkonian *et al.*, 1999). How do rafts form in cytosolic leaflets? Our knowledge of lipid asymmetry is very incomplete. Perhaps some fraction of inner leaflet lipids are more saturated than generally thought, and thus can help form rafts. A different, long-held notion is that there is interleaflet coupling of lipid physical properties such that lipids organized into Lo domains in the exofacial leaflet might induce Lo state domains in the cytosolic leaflet. Studies using planar lipid bilayers (unsupported or cushioned supported) or lipid vesicles have shown that coupling can be detected in asymmetric model membranes when one leaflet contains SM or a saturated phospholipid and the other does not, and that acyl chain structure can modulate coupling (Chiantia and London, 2012; Collins and Keller, 2008; Wan *et al.*, 2008). However, the details of the relationship between lipid structure and coupling remain largely uncharacterized.

It should also be noted that membrane proteins could influence raft formation and interleaflet coupling. A protein that has a favorable affinity for rafts by definition contributes to the free energy of raft formation, and can even trigger raft formation in situations in which rafts formed by lipids alone would have a borderline stability (see below).

The Basis of Membrane Protein Interaction with Rafts

How and when proteins interact with lipid rafts is central to raft function. Localization of different proteins to rafts could increase protein-protein interaction, while segregation into different domains would prevent their interaction. In addition, the different physical properties of lipid domains (in terms of bilayer width and molecular packing) could support different conformational states for proteins in Lo and Ld domains.

Association of lipid-anchored peripheral proteins with Lo domains is likely to be driven by tight packing between the saturated acyl chains attached to proteins and the lipids in Lo domains (i.e., saturated acyl chain sphingolipids and cholesterol) (Schroeder *et al.*, 1994). Many palmitate and myristate anchored proteins that insert into the cytosolic leaflet of membranes have a significant affinity for rafts (Levental *et al.*, 2010; Melkonian *et al.*, 1999; Wang *et al.*, 2001). In contrast, proteins covalently anchored by hydrocarbon chains that pack poorly into ordered domains, such as unsaturated acyl chains and polyisoprene chains have low affinity for Lo domains (Lindwasser and Resh, 2002; Melkonian *et al.*, 1999; Moffett *et al.*, 2000; Wang *et al.*, 2001). Furthermore, GPI-anchored proteins from mutant cells producing GPI anchors with unsaturated acyl chains lose association with DRM, suggesting lower raft affinity (Maeda *et al.*, 2007).

Similar considerations apply to peripheral membrane proteins that associate with lipids non-covalently. For example, the strong affinity of cholera toxin for the sphingolipid ganglioside, ganglioside M1 (GM1), is clearly the source of the strong interaction of cholera toxin with ordered domains (Dietrich *et al.*, 2001), and cholera toxin trafficking in cells is significantly altered when GM1 is anchored by acyl chains that do interact well with rafts (Chinnappen *et al.*, 2012). Raft affinity arising from lipid binding appears to be true for other glycosphingolipid binding proteins (Kovbasnjuk *et al.*, 2001).

Nevertheless, it should be noted that the absolute affinity of saturated lipid anchors for ordered domains is not necessarily very strong (Wang *et al.*, 2001), and is likely to be dependent on the actual lipid composition of the ordered and disordered domains. In cells, oligomerization of lipid-anchored proteins that only weakly associate with rafts as monomers may greatly increase raft affinity (Brown and London, 1998; Harder *et al.*, 1998), but this has not been seen in every example studied (Keller *et al.*, 2013).

The origin of the affinity of integral transmembrane (TM) proteins for rafts has been more difficult to define. The rough surface of a TM helix should not favor very strong van der Waals interactions with lipid acyl chains, and should favor association of TM proteins with Ld domains. Indeed, several studies with single TM helices have reported a stronger affinity for Ld relative to Lo domains (Fastenberg *et al.*, 2003; Shogomori *et al.*, 2005; van Duyl *et al.*, 2002; Vidal and McIntosh, 2005). However, many TM proteins have been reported to associate with rafts. One explanation involves hydrophobic mismatch between TM segment length and the width of the hydrophobic portion of the bilayer. Lo domains generally form a wider lipid bilayer than do Ld domains (Figure 1). If hydrophobic TM segment length exceeds bilayer width, i.e., if there is positive mismatch, then unfavorable exposure of hydrophobic residues to a polar environment could occur. This unfavorable exposure would be less in Lo domains, thus favoring association with Lo domains. Early studies of mismatch may have been defeated by the ability of single TM helices to tilt in thin bilayers, thus circumventing positive mismatch. However, when perfringolysin O (PFO), a protein with multiple TM segments and which cannot avoid mismatch by tilting, was engineered to have longer and shorter lengths, it was found that mismatch can indeed control association with Lo domains (Lin and London, 2013a). It is possible that a reduced ability to tilt upon helix oligomerization may dynamically regulate TM protein raft affinity in some cases. In this regard it is noteworthy that oligomerized aquaporins show a stronger affinity for Lo domains than aquaporin monomers (Tong *et al.*, 2009). The effect of oligomerization upon raft affinity could also explain the common observation that raft affinity seems to increase upon activation of biological processes that assemble TM protein signal transduction complexes.

Another factor controlling the raft affinity of TM proteins may be attachment or binding to specific raft-associating lipids. In the case of the TM state of PFO, a protein which non-covalently binds to sterols, association with rafts is dependent upon the raft affinity of the sterol to which it is non-covalently bound (Lin and London, 2013b). Also, a functionally important interaction of the epidermal growth factor receptor (EGFR) protein with GM3 has been reported, and may impart affinity for ordered domains (Coskun *et al.*, 2011). Many TM proteins are covalently palmitoylated, and the packing of the palmitoyl group with Lo domains could contribute to raft affinity (Levental *et al.*, 2010). Indeed, blocked palmitoylation is associated with reduced raft affinity (Levental *et al.*, 2010). However, it has been difficult to confirm whether this involves a direct effect upon raft affinity, because in model membranes the effect of palmitoylation upon TM helix raft affinity has been small at most (Shogomori *et al.*, 2005; van Duyl *et al.*, 2002). This might reflect a loss of TM helix oligomerization in model membranes, or inexact mimicking of natural membranes (in these cases, plasma membrane) by the model membranes used. It is also possible that palmitoylation influences raft affinity indirectly, for example, by altering the depth of membrane immersion by a TM segment, and thus by factors such as hydrophobic mismatch or altering the subcellular membrane in which a protein is localized.

For extrapolating TM raft affinity from model to real membranes, lipid asymmetry may be an important issue. Suggestively, it has been reported that plasma membrane proteins exhibit an amino acid asymmetry in the inner and outer leaflet segments of TM sequences (Sharpe *et al.*, 2010). Thus, it is possible that differences in packing in the exofacial and cytofacial leaflets influences protein behavior, and thus raft affinity. The recent development of model membrane planar bilayers and vesicles with lipid asymmetry should make it possible to address this issue (Cheng *et al.*, 2009; Cheng and London, 2011; Chiantia and London, 2012; Collins and Keller, 2008; Hussain *et al.*, 2013; Lin and London, 2014; Wan *et al.*, 2008).

It should also be kept in mind that some membrane proteins may prefer to locate at the edges of lipid domains (Lin and London, 2013a). This would allow them to interact with proteins that are both inside and outside of domains.

Figure 1 Schematic illustration of coexisting raft and non-raft domains. Raft-favoring lipids are shown with gray polar headgroups, and are enriched in raft domain. Note raft lipids are more tightly packed and ordered and tend to form a bilayer with a thicker width than the more disordered, loosely packed non-raft domain lipids. Raft-associating proteins are either saturated acyl chain lipid-anchored (oval) or are transmembrane (rectangle) with hydrophobic amino acid surfaces favoring raft association, for example, having a wide hydrophobic surface (black band) that matches the width of the hydrophobic portion of the raft domain lipids. Non-raft protein (triangle) has a hydrophobic surface that matches thinner width of non-raft domain lipids.

Lipid Domain Size

Under most conditions, lipid domains are submicroscopic. Attempts to measure domain size in cells using methods such as single-particle tracking, various lateral diffusion measurements, and super-resolution microscopy have not provided a single accepted value for domain size but have led to the thinking that rafts in cells are generally very small, perhaps sometimes as small as a few nanometers (Anderson and Jacobson, 2002; Brown and London, 1998). However, cell membrane domains rich in a particular lipid can sometimes be large enough (micron sized) to visualize by ordinary microscopy. These may represent large domains, or just regions richer in submicroscopic raft domains than the remainder of a membrane. In addition, because membranes are dynamic, a particular region in a membrane may simply be transiently enriched in a particular lipid because of local metabolic processes such as localized synthesis or delivery from internal organelles, rather than possess stable domains. Regions of spectroscopically identified increased membrane order that are large enough to detect by ordinary microscopy are more likely to be indicative of the presence of Lo domains, especially when raft-associated molecules co-localize with such regions (Gaus *et al.*, 2006a). This may again represent a region rich in very small raft domains, rather than a single raft.

Studies of domain size in model membranes are helpful for studying control of domain size in cells. In vesicles composed of mixtures of high-T_m saturated lipids, low-T_m unsaturated phospholipids, and cholesterol, multimicron size coexisting Lo and Ld domains can often be observed by microscopy (Hammond *et al.*, 2005; Veatch and Keller, 2003). However, lipid domain size in model membranes is highly lipid structure and temperature dependent, and can be as small as a few nanometer scale (Brown *et al.*, 2007; Pathak and London, 2011; Petruzielo *et al.*, 2013). Detecting separation of lipids into different domains in binary mixtures of one lipid and cholesterol has been more difficult to detect than in ternary mixtures of high-T_m lipid, low-T_m lipid, and cholesterol, although nuclear magnetic resonance (NMR), electron spin resonance (ESR) imply that domains form in binary mixtures (Sankaram and Thompson, 1990; Vist and Davis, 1990). Domains in binary mixtures may be extremely small or highly transient.

Why nanodomains form is not well-understood. If the energy of lipid demixing is favorable, small domains should coalesce into a single large domain because this would minimize the number of lipids at the energetically unfavorable boundaries between domains, at which lipids in different domains are in contact. The 'critical fluctuation' model proposes that tiny domains only exist at compositions and temperatures just above that at which phase separation is stable, i.e., just above a critical point, and then decrease in size as temperature is further increased (Veatch *et al.*, 2007, 2008). Consistent with this, nanodomain size decreases as temperature increases (Pathak and London, 2011). However, in some ternary lipid mixtures nanodomains predominate under a wide range of lipid compositions (Feigenson and Buboltz, 2001; Petruzielo *et al.*, 2013). Also, they can behave like miniature true phases, as judged by their different affinities for various fluorescent probes that are similar to those in large

scale phases (Pathak and London, 2011). It is possible that there is some interaction counteracting the tendency of domains to coalesce. A long standing idea has been that some lipids may have favorable energetic interactions at domain edges, which would favor small domains, which have a large circumference to area ratio. However, it is not clear to what extent this is important (Hassan-Zadeh *et al.*, 2014; Heberle *et al.*, 2013). Another factor likely to influence size is the extent of mismatch between the widths of the bilayer in different domains. The smaller the mismatch, the smaller the energetic penalty (line tension) at domain boundaries, which would lead to a smaller domain size (Heberle *et al.*, 2013). In contrast, clustering of raft preferring molecules by crosslinking tends to increase domain size or even trigger phase separation (Hammond *et al.*, 2005; Harder *et al.*, 1998; Lingwood *et al.*, 2008). Other possible biophysical influences on domain size have been proposed (Amazon *et al.*, 2013; Shlomovitz and Schick, 2013).

Raft size is an important issue when considering how they may influence protein-protein interactions. Unlike the situation in large raft domains, very small raft domains with only a single protein molecule could not enhance interactions between two different raft-associated proteins. However, they might enhance interaction between proteins in different domains, if proteins in different domains can approach close enough to establish contact. Raft size could also affect protein-protein interactions involving proteins that prefer to locate at the boundary between raft and non-raft domains (edges may have an intermediate bilayer width relative to Lo and Ld domains, and can attract TM proteins with a matched hydrophobic width (Lin and London, 2013a)). In this regard it is noteworthy, that some TM proteins surrounded by a layer or two of Ld lipids could form tiny Ld nanodomain inclusions within a raft domain (Almeida *et al.*, 2005; London, 2005; Nelson *et al.*, 2010; Polozova and Litman, 2000). The ability of Ld state lipids to stretch could allow formation of Ld inclusion thicker than bulk Ld domains, and even matching the surrounding Lo domains in thickness (Nelson *et al.*, 2010).

In cells, dynamic changes in lipid composition must also be considered. It is unlikely that this could prevent the formation of small domains, which do not need large-scale movements of lipids, but could limit the establishment of equilibrium conditions that drive the coalescence of small domains into larger ones.

Little is known about temporal persistence of domains. Large domains are clearly long-lived. The situation for nanodomains is less clear. Lo nanodomains can clearly persist long enough to have partition properties (i.e., affinities for other molecules) that are similar to large Lo phases. In addition, proteins that strongly associate with Lo or Ld domains may not only nucleate domain formation, but lengthen domain persistence. This is an important issue because domains persisting for only milliseconds might not be able to regulate protein function.

Detecting Rafts in Model Membranes

Formation of coexisting ordered and disordered domains in model membrane vesicles (liposomes) is readily detected, and

large domains can be readily visualized by microscopy for a wide variety of lipid mixtures (Korlach *et al.*, 1999). Submicroscopic domains can be detected by a calorimetry and a wide variety of spectroscopic methods (Heberle *et al.*, 2010; Pathak and London, 2011; Petruzielo *et al.*, 2013). However, an important consideration is that different methods have different special resolutions (Petruzielo *et al.*, 2013). When domains are not detected by one spectroscopic method, it does not prove they do not exist; they may just be below the resolution limit of that method. The fact that a liquid–liquid phase separation has formed is readily ascertained from domain shapes (rounded) (Samsonov *et al.*, 2001) and properties such as lateral diffusion, which is very slow in the solid-like gel states relative to Ld or Lo states (Almeida *et al.*, 1992; Rubenstein *et al.*, 1979). Based on such measurements, phase diagrams, which give the lipid composition and abundance of each type of domain as a function of overall lipid composition and temperature, have been formulated for several raft-forming ternary lipid mixtures containing cholesterol (Konyakhina *et al.*, 2013; Petruzielo *et al.*, 2013). Sometimes, different phase diagrams have been proposed for identical lipid mixtures by different groups, probably because methods with different special resolutions have been used.

Detecting Rafts in Natural Membranes: Giant Plasma Membrane Vesicles

In contrast to the situation in model membranes, rafts have been difficult to visualize in cells. An important advance in the field has been the studies of rafts in natural giant plasma membrane vesicles, giant plasma membrane vesicles (GPMV) (Baumgart *et al.*, 2007). These vesicles and closely related plasma membrane spheres (PMS), can be prepared from cell plasma membranes by methods that involve mild-to-moderate treatments (Baumgart *et al.*, 2007; Lingwood *et al.*, 2008). The vesicles are large enough for microscopy, and maintain natural membrane complexity in terms of lipid and protein composition, although cytoskeletal connections are lost, lipid composition mildly perturbed, and lipid asymmetry at least somewhat compromised (Keller *et al.*, 2009). At lower temperatures classical large Lo domains can be easily visualized in these vesicles by microscopy. This shows that the heterogeneity induced by the mere presence of hundreds of different lipids and proteins is insufficient to block lipid domain formation. In addition, in many cases the association of putative raft-associated proteins with the Lo domains in GPMV parallels that in simple giant unilamellar vesicle (GUV) and that defined by other methods (e.g., detergent insolubility) (Keller *et al.*, 2009; Sengupta *et al.*, 2008). However, the absolute affinity for Lo state domains is not identical in GPMV and simple GUV (Keller *et al.*, 2009). It is not clear why large domains are seen much more readily in GPMV than cells, but some factor connected to a loss of cytoskeletal connections is one possibility. Although domain size in GPMV shrinks as temperature is increased, it is likely that submicroscopic domains persist to physiological temperatures. In addition, formation of large Lo domains can be readily triggered in PMS at physiological temperatures by clustering events, for example, induced by addition of cholera toxin (Lingwood *et al.*, 2008).

Using Detergents to Detect Rafts in Cells: Rationale and Limitations

The first method to detect rafts in cells was detergent insolubility (Brown and Rose, 1992). Detergents (especially Triton X-100) have been widely used to isolate DRM fractions that might arise from lipid rafts. The rationale is that loosely packed Ld state membranes dissolves in detergent while tightly packed ordered membranes (gel and Lo) tend to be insoluble in detergent (London and Brown, 2000; Schroeder *et al.*, 1994). This is easily explained in terms of the stronger lipid–lipid interactions in tightly packed domains. Spectroscopic studies studying the association of protein and lipid with ordered domains in model membranes show a marked correlation with their affinity for DRM (Dietrich *et al.*, 2001; Wang *et al.*, 2001). However, binding of detergent to membranes changes membrane structure and thus can perturb the lipid composition and properties of the lipid domains. For this method to work properly the detergent has to dissolve the Ld domains before membrane rearrangements can occur (London and Brown, 2000; Nelson *et al.*, 2010; Schroeder *et al.*, 1994).

Many studies in model membranes have shown that upon addition of detergent to membranes with coexisting ordered and Ld domains there is selective solubilization of Ld domains, which suggests little perturbation of domain formation by detergent. However, interactions with detergent can be lipid composition specific, and when lipids form small membrane domains (e.g., in SM, 1-palmitoyl 2-oleoyl phosphatidylcholine (POPC), cholesterol mixtures) they might be particularly susceptible to perturbation by detergent. It has been reported that Triton X-100 can increase immiscibility of POPC and SM in cholesterol-containing membranes, and thus induce domain segregation under conditions in which it would not form otherwise (Heerklotz, 2002; Heerklotz *et al.*, 2003). However, a subsequent study reported that in SM, POPC, cholesterol mixtures TX-100 does NOT increase immiscibility or induce domain formation, but rather induces coalescence of pre-existing ordered nanodomains (Pathak and London, 2011). Coalescence into large domains is of less concern than artifactual domain formation, and is a necessary property for formation of DRM which can be readily isolated.

Nevertheless, concerns about the use of detergents remain. In some cases, but not all, DRM association can reflect rearrangements after solubilization (London and Brown, 2000; Nelson *et al.*, 2010; Schroeder *et al.*, 1994). Appropriate controls are necessary (Nelson *et al.*, 2010; Schroeder *et al.*, 1994). Another complication is under some experimental conditions (e.g., too low a detergent to lipid ratio), detergents like Triton X-100 can incompletely dissolve Ld domains, and can sometimes dissolve ordered domains, especially those with low or no cholesterol (London and Brown, 2000). As a result, interpreting differences obtained when diverse detergents or conditions are used is problematic. Finally, solubilization is usually carried out at 4 °C, and low temperature can certainly induce formation of ordered domains that would not exist at physiological temperature, for example, 37 °C. In this regard, methods to carry out solubilization at 37 °C are promising (Drevot *et al.*, 2002; Morris *et al.*, 2011). Methods to fragment membrane into raft and non-raft domains without using detergent are also sometimes used (Macdonald and Pike, 2005),

perhaps aided by domain coalescence under conditions of membrane tension (Ayuyan and Cohen, 2008) although the efficiency of these methods in terms of separating Lo and Ld domains is often uncertain. It has also been found that physical fragmentation of membranes after adding beads binding a protein with a strong raft affinity isolate raft-type lipids but control beads binding a non-raft protein do not (Zech *et al.*, 2009).

To summarize, DRM studies represent a useful starting point in studies of lipid raft in cells, and can provide an idea about the raft affinity of different molecules, and changes in raft affinity in different physiological states. However, they cannot be relied upon on their own to define when rafts are present in cells or the exact extent to which a specific molecule is or is not raft-associated under physiological conditions. Other methods must be used in conjunction with detergent solubilization.

Detecting Rafts in Cells: Microscopy and Spectroscopy

As noted above, in intact cells, apparent membrane domains, which may be single domains or regions rich in a large number of nanodomains, can sometimes be visualized by microscopy, especially when raft-associating molecules are clustered. It is important to note that a portion of a cell having more membrane lipid per unit volume than other regions (e.g., due to submicroscopic membrane irregularities) will show an increased local concentration of all membrane molecules that can be mistaken for co-localization of proteins in rafts (Glebov and Nichols, 2004). It is important to show depletion of non-raft molecules in a region enriched in raft-forming molecules before concluding that there is co-localization of a protein with a raft.

A variety of advanced microscopy methods have been used to detect rafts in cells. Membrane-bound fluorescent probes (e.g., Laurdan and di-4-ANEPPDHQ) that have distinct spectroscopic signal when associated with regions having elevated membrane order have been widely used to detect domains (Dietrich *et al.*, 2001; Gaus *et al.*, 2003, 2005, 2006b; Harder *et al.*, 2007; Owen *et al.*, 2006, 2007; Zech *et al.*, 2009) and new probes are being steadily introduced (Klymchenko and Kreder, 2014). Because of the small size of rafts, super-resolution microscopy has the promise of more facile raft detection (Honigsmann *et al.*, 2013, 2014; Sezgin *et al.*, 2012). However, raft size may often be below the resolution level achievable using this method. Microscopy methods based on mass spectrometric analysis of lipid composition have recently been used to detect lipid heterogeneity in cell membranes (Frisz *et al.*, 2013), but again resolution may be an issue. Single-particle tracking and lateral diffusion methods can be used to detect domains via their effect on reducing or confining diffusion (Lenne *et al.*, 2006; Pinaud *et al.*, 2009; Suzuki *et al.*, 2012). The fact that other membrane properties may affect diffusion can complicate interpretation of such experiments. Finally, fluorescence resonance energy transfer (FRET) methods suitable for use in cells have also been able to detect domain formation (Sengupta *et al.*, 2007; Sohn *et al.*, 2008). Depending on donor and acceptor used, FRET should be able

to detect all but the smallest of nanodomains (Pathak and London, 2011). However, FRET requires that the donor and acceptors have suitable affinities for the domain type in question.

Despite all these issues, some recent microscopy studies provide relatively compelling evidence for lipid rafts in living cells. Large-scale domain separation in yeast vacuoles which exists in the absence of any clustering of raft-markers has been observed (Toulmay and Prinz, 2013). The domains appear almost identical in scale to those seen in GUV with Lo domains, with the rounded shapes characteristic of liquid-liquid phase separations as seen in membranes with coexisting large Ld and Lo phases. In the bacterium *Borrelia burgdorferi*, raft-like domains have been observed that are large enough to easily visualize using transmission electron microscopy (LaRocca *et al.*, 2010, 2013). These domains can also be detected in living *Borrelia* using FRET, and detected biochemically by isolation of DRM (LaRocca *et al.*, 2010, 2013). They appear to be equivalent to eukaryotic lipid rafts based upon their selective affinity for saturated vs. unsaturated lipids and because the presence of raft-forming sterols are necessary and sufficient for their formation (see below).

Detecting Rafts in Cells Using Sterol Modification

One common method to identify likely raft-dependent functions is to define biological processes inhibited upon (partial) extraction of cholesterol from cells using cyclodextrins (Zidovetzki and Levitan, 2007). Restoration of function by replenishment of cellular cholesterol using cholesterol-cyclodextrin complexes is then used to demonstrate that it is extraction of cholesterol that altered function. These studies have the limitation that sterol extraction, which changes overall mass balance in the membrane, changes more than just raft levels. It is also claimed that the loss of DRM upon sterol extraction demonstrates that rafts have been destroyed by cyclodextrin treatment, but this is not correct. Ordered domains with low levels of sterol or no sterol can sometimes dissolve in Triton X-100 (London and Brown, 2000).

A more reliable, albeit more complex, approach involves sterol substitution. The abilities of various sterols and steroids to stabilize or destabilize raft formation have been defined (Megha *et al.*, 2006; Wang *et al.*, 2004; Wenz and Barrantes, 2003; Xu and London, 2000; Xu *et al.*, 2001). In sterol substitution partial extraction of cellular sterols is followed by replenishment with a diverse series of exogenous sterols with different raft-forming abilities. Overall lipid mass balance can be (roughly) maintained in these experiments. When there is a strong correlation between a biological process and the raft-forming ability of sterols with diverse chemical structures, then it becomes likely that the biological process is raft-dependent. To be more precise, if every raft-stabilizing sterol supports a function while every raft-destabilizing sterol does not, and there are no other properties that distinguish function-supporting from the function-inhibiting sterols, then it can be inferred that a sterol having raft-stabilizing properties is both necessary (i.e., function is not supported by raft-destabilizing sterols) and sufficient (i.e., function is supported by all raft-stabilizing sterols) for the function. This pattern establishes

raft-dependence as the favored working hypothesis for the process under study. Perhaps just as important, by identifying biological processes that do not show this pattern, sterol substitution is an efficient approach to define processes unlikely to be raft-dependent (Singh *et al.*, 2009). A similar strategy is to introduce other molecules that should stabilize or destabilize rafts into membranes, such as polyunsaturated fatty acids or ceramides (Gidwani *et al.*, 2003; Zech *et al.*, 2009). In all such studies additional issues to consider include rapid metabolic transformations of the added molecules and signaling events that such molecules may trigger.

Several sterol substitution studies have been carried out. Sterol substitution studies in the bacterium *B. burgdorferi* show raft properties were necessary and sufficient for domain formation. These studies were especially informative because ordered lipid domains can readily be detected in this organism by electron microscopy and FRET (LaRocca *et al.*, 2010, 2013). In addition, sterols having raft-stabilizing properties were necessary and sufficient to maintain membrane integrity in *B. burgdorferi* (LaRocca *et al.*, 2013). In T cells, 7-ketocholesterol has been substituted for cholesterol. The raft-forming abilities of 7-ketocholesterol may only be slightly weaker than those of cholesterol (Wang *et al.*, 2004), but the difference appears to be sufficient to disrupt raft formation and T cell signaling (Rentero *et al.*, 2008). In the case of HIV, it has been shown that substitution of raft-destabilizing sterols into virions inhibits infectivity while substitution of raft-stabilizing sterols does not (Campbell *et al.*, 2004).

Biological Functions of Raft Domains in Cells

It has been reported that lipid rafts are associated with almost every process involving cell membranes. Given this, the diverse criteria that have been used to assign whether a particular function is raft dependent and the disagreements about what methods prove that rafts exist under a particular set of conditions, an extensive discussion of claimed raft functions is beyond the scope of this article.

Although there are few, if any, membrane functions, in which every study supports a role for lipid rafts, there are several topics in which a preponderance of studies indicate that ordered lipid domain formation is likely to play an important functional role. One is in sorting of molecules to different membranes. Fluorescent probes and lipid-anchored proteins can be sorted to a degree or rate that is dependent upon whether they are attached to Ld or Lo associating lipids (Mukherjee *et al.*, 1999; Refaei *et al.*, 2011). In this regard, the observation that sorting vesicles targeted to plasma membrane are richer in Lo lipids than the membrane from they arise may be relevant (Surma *et al.*, 2011). The difference in Lo and Ld domain bendability is likely to be involved in membrane shape-dependent domain formation. In this regard, studies in model membrane vesicles have shown that formation of tubules from large vesicles, a common event in sorting, can induce domain formation/segregation (Roux *et al.*, 2005).

The second important function is signaling, especially in the immune system. Studies have implicated rafts having a role in organizing immune system proteins in response to stimulation in mast, T and B cells. In T cells, a wide variety of

studies have been carried out. Assembly of activated T cell receptor and associated proteins into rafts upon activation has been detected and assessed by isolation techniques without use of detergent, association with fluorescently detected ordered regions of the lipid bilayer, sterol alterations, and temperature perturbation methods (Harder and Sangani, 2009; Harder, 2012; Magee *et al.*, 2005; Mahammad *et al.*, 2010; Rentero *et al.*, 2008; Zech *et al.*, 2009), although it has also been found that clustering of both raft and non-raft lipids can induce T cell signaling (Wang *et al.*, 2005). In B cells both detergent insolubility and FRET methods have detected raft association, and FRET shows that raft association is an intermediate event in activation (Liu *et al.*, 2010). In mast cells, clustering in rafts may trigger signaling, and be involved in segregation of kinases and phosphatases (Holowka *et al.*, 2005). Rafts may also be involved in many other signaling processes (Simons and Toomre, 2000).

Rafts seem to have a role in certain types of infection. HIV and influenza infection have been most extensively studied in this regard (Rossman *et al.*, 2010; Veit *et al.*, 2013; Waheed and Freed, 2009). Raft interactions during infection or viral assembly can be important. However, differences in viral protein behavior in cells and model membranes complicate our understanding of the molecular role of rafts in these cases.

Two other areas in which the participation of rafts has been extensively investigated are the formation of amyloid from APP protein in studies of Alzheimer's disease and in sperm cell membrane structure and maturation (Nixon and Aitken, 2009; Vetrivel and Thinakaran, 2010). It is also possible that altered rafts are involved in diseases of cholesterol biosynthesis, such as Smith-Lemli-Opitz syndrome (Megha *et al.*, 2006; Nowaczyk and Irons, 2012).

A problem in defining the role of rafts in cells is that studies of protein association with rafts in model membranes and cells do not always agree (Keller *et al.*, 2013; Nikolaus *et al.*, 2010; Veit *et al.*, 2013). This may reflect the fact that model membrane vesicles are not always good mimics of cell membranes. Model membranes lack the high protein concentration and cytoskeletal proteins found in natural membranes. Also, they tend to have simple lipid compositions and generally use cholesterol concentrations lower than that in plasma membranes. However, the most serious problem may be that most model membranes lack the lipid asymmetry characteristic of natural membranes. Recent advances in forming highly asymmetric planar membranes and vesicles that closely mimic cell membranes (Cheng *et al.*, 2009; Cheng and London, 2011; Hussain *et al.*, 2013; Lin and London, 2014; Wan *et al.*, 2008) suggest future studies in model membranes may reveal domain behavior even closer to that in cells.

Membrane Potential: Concepts

AJ Moorhouse, UNSW Australia, Sydney, NSW, Australia

Introduction

Everything we do, from playing a challenging piano concerto or sprinting in a 100 m race, or even simply walking and breathing and admiring the birds and trees, involves a complex array of muscle activity and sensory inputs all coordinated by the brain and nerves. As we eat and metabolize our food, sleep and grow from fertilization to maturity, our digestive and endocrine systems regulate our bodies and maintain homeostasis under very different environments. Our respiratory and cardiovascular systems provide the energy to maintain our bodily functions. All of these wonderful activities rely on cellular functions that depend on changes in the small voltage difference across the thin plasma membrane that encapsulates all animal cells, the 'membrane potential.' This 20–100 mV gradient across our cell membrane is a key component to cell and body function, and a large fraction of our cellular energy is spent on establishing and regulating this transmembrane voltage. In this article, the author reviews the principles of how membrane potentials are generated by the combination of selective membrane permeability and ion electrochemical gradients. Section 'Introduction' will provide some basic principles regarding electrical and chemical properties of ions and cell membranes, section 'Determinants of the Membrane Potential' will build on this to describe more specifically how membrane potentials arise as a consequence of electrochemical gradients and selective membrane permeability, and section 'Measuring Membrane Potential and Relative Membrane Permeability' will review approaches to measure membrane selectivity and membrane potentials, providing some exemplar values from the literature.

Definitions of Different Types of Membrane Potentials and Related Terminology

The following list defines some of the different types of membrane potentials, and some related terminology. The article assumes familiarity with these terms (Box 1).

Physical–Chemical Properties of the Cell Membrane and Physiological Solutions

The membrane potential, like any voltage difference, reflects a different electrical charge from one point to another point. In this case, the uneven charge distribution is across the cell membrane, from the intracellular surface of the membrane to the extracellular surface of the membrane. This arises due to a different concentration of charged ions on each side of the membrane. So an important introductory concept is that in biology, positively charged cations and negatively charged anions contribute to the charge on either side of the cell membrane, and the flow of charge (or current) across the

membrane is carried by the movement of ions across the membrane. To understand this, we first need to review some simple aspects of electricity and of physical chemistry.

A crystal of common table salt, or NaCl, contains Na and Cl atoms bound tightly together in a lattice bound by ionic bonds. The Na atom loses its electron to the Cl atom to give rise to Na^+ and Cl^- ions. When a pinch of salt is placed into water, the ionic bonds are disrupted by electrical interactions between water and the ions, and the salt crystals dissociate into hydrated Na^+ and Cl^- ions, that is the ions surrounded by a shell of water molecules (Figure 1(a)). The water molecules are 'polar,' meaning that the distribution of electrons is not evenly spread across the H_2O molecules – the electrons spend more time around the oxygen atom as compared to the two hydrogen atoms. Hence the oxygen in water has a partial negative charge, while the hydrogen atoms have a partial positive charge. Ions are energetically unstable in isolation but are stabilized in solution by being surrounded by water orientated accordingly with Na^+ ions surrounded or shielded by negative oxygen water molecules, while the Cl^- anion is surrounded by water with the positive hydrogen facing the

Box 1

Membrane potential (V_m): A difference in voltage across the cell membrane arising due to small difference in the distribution of ions in the intracellular and extracellular solutions. Defined as intracellular voltage with respect to extracellular voltage.

Resting membrane potential: The membrane potential during a period when the cell is not active or being stimulated. Typically, a stable, steady-state condition of about -80 to -60 mV. Note however that many cells have an unstable or fluctuating resting V_m that if in a regular pattern can be called pacemaker activity.

Action potential: A basic unit of cell signaling that involves a transient and rapid change in membrane potential. Although the time course and amplitude of this V_m change varies widely in cells, in many nerve and muscle cells V_m changes from about -70 mV up to about $+20$ mV before returning to -70 mV.

Depolarization: A change in the V_m in a positive direction. Typically increases the probability of a cell firing an action potential, hence typically excitatory.

Hyperpolarization: A change in the V_m in a negative direction. Typically decreases the probability of a cell firing an action potential, hence typically inhibitory.

Repolarisation: A return of the membrane potential to resting value following a large depolarization, such the hyperpolarisation phase of the action potential

Synaptic potential: A change in membrane potential in a postsynaptic cell arising from action of a neurotransmitter released by a presynaptic nerve. It can be in the hyperpolarising direction (an inhibitory postsynaptic potential) or in a depolarizing direction (an excitatory postsynaptic potential).

Sensory potential: A change in the membrane potential of a sensory receptor neuron arising due to a change in a sensory modality input (touch, smell, taste, vision, and hearing).

Figure 2 Electrical circuits: hardwired vs. biology. (a) Schematic diagram of an electrical circuit showing a car battery connected via a wire and switch to two car headlights/lamps. The battery has a different distribution of charges providing a negative and positive pole (cathode and anode, respectively) that drives current in the form of electrons through the wire conductor. Current only flows when the switch is closed to complete the circuit. Current flows through the resistance provided by the lamp filaments, heating the filaments to cause the response – light. Available at: <http://electricalengproject.blogspot.com.au/2012/06/electrical-circuits.html> (accessed 17.02.15). (b) In biology, the electrical battery is equivalent to the membrane potential with a negative charge (cathode) on the inside and a positive charge (anode) outside. When a switch (ion channel) is open, current in the form of charged ions can flow into the cell to cause a response – a depolarization.

anion. Molecules, like ions, that are readily dissolved in water (or become hydrated by water) are said to be ‘hydrophilic.’

In contrast to water, the interior of the cell membrane is ‘nonpolar’ and ‘hydrophobic.’ The long hydrocarbon chains of the lipid molecules that comprise the membrane have no partial charges and cannot readily dissolve in water. This is readily seen when oil is spilled into water by the way oil forms a film floating on the surface of the water. Nonpolar molecules will however readily interact with other nonpolar molecules (just as polar molecules readily interact). Hence the hydrated ions cannot freely pass through the cell membrane due to this nonpolar lipid core. The energetics of moving an ion from an aqueous solution (with a high dielectric constant of ≈ 80) to the interior of the lipid bilayer (with a dielectric constant of ≈ 2) is so high that less than 1 in 10^{50} ions would partition into the membrane (Coster, 2003). The lipid bilayer can therefore readily sustain a charge separation corresponding to a physiological V_m of $\pm 100 \text{ mV}$. As the membrane is only 5–10 nm thick, this corresponds to a very large electric field strength ($\approx 10^7 \text{ V m}^{-1}$), demonstrating the strong insulating capacity of the lipid bilayer. If the V_m is artificially increased to a few hundred mV, say to 400 mV, the membrane may transiently break down. This ‘punchthrough’ or dielectric breakdown may become irreversible if even larger voltages are applied across the membrane (1 V or more). The voltage-induced transient membrane rupture has actually been utilized

to enable large molecules to be inserted into the cell by electroporation (Coster, 2009).

If the hydrocarbon tails of lipids are nonpolar, how can they exist bathed by the polar salt solutions that comprise intracellular and extracellular solutions? The answer is that the lipid molecules that make up mammalian cell membranes are phospholipids and ‘amphiphilic,’ containing polar headgroups attached to the nonpolar hydrocarbon tails (Figure 1 (b)). The polar headgroups can readily interact with water. These phospholipids will spontaneously adopt a bilayer configuration when placed in a polar solvent such as water – the nonpolar tails will join up and the polar headgroups will form the border with the polar solvent. Hence the plasma membrane of a mammalian cell contains a phospholipid bilayer which physically and electrically separates the intracellular and extracellular solutions. Within this bilayer membrane are inserted numerous proteins which function as membrane transport proteins, enzymes, and receptors to communicate with other cells.

Electrical Properties of the Cell and Ohm’s Law

Consider a simple hardwired electrical circuit such as that found in a hand-held torch or car battery (Figure 2(a)). The driving force for providing electrical current through this

Figure 1 Schematic structures of hydrated ions and the cell membrane lipids. (a) Schematic diagram of a crystal of common table salt (NaCl; upper panel) with the Na^+ and Cl^- bound in a tight ionic lattice. Upon addition of the polar water (H_2O) molecule, the Na^+ and Cl^- separate and become hydrated ions (lower panels). Reproduced from Allman, R. A helpful introduction to polar and nonpolar molecules. The chemistry webpages of Robert Allman. Available at: <http://www.chemstone.net/Principles/7.Solutions/Soln.html> (accessed 17.02.15). (b) Schematic diagram of a single typical membrane phospholipid molecule (this example is ‘phosphatidylcholine’) showing its chemical structure and a schematic depiction of its hydrophobic fatty acid tail, and its polar head (phosphate and choline), joined by the glycerol backbone. The lower right panel depicts a lipid bilayer such as that which forms the cell membrane, with the nonpolar tails joined together, and the polar head groups facing the extracellular and intracellular solutions. Figure accessed from the CK-12 Foundation under a creative commons CC BY-NC license (<http://www.ck12.org/biology/Phospholipid-Bilayers/lesson/Phospholipid-Bilayers/>).

circuit illustrated in [Figure 2\(a\)](#) is a 12 V battery. A copper wire that connects the two poles of the battery – the cathode and anode – acts as a conductor of the electrical current. The current is movement of charge in the form of electrons traveling along this conductor. The switch is a break in the wire that only allows current to flow when the circuit between the cathode and anode is complete. The resistance of the circuit is determined by factors such as the thickness, length, and conductivity of the wire, and in this case by the properties of the high-resistance filament placed in series in this circuit. When the switch is on, current flows through the circuit driven by the potential difference (voltage) of the battery, and the filament heats up and provides light to mediate the car headlamp or torch's function.

In biology, the principles are just the same but the elements are different ([Figure 2\(b\)](#)). The circuit is the flow of current across the membrane. The current is carried by ions flowing through the circuit. The battery providing the driving force for ionic current flow is the 'electrochemical driving force' for the ion that carries the current. This concept is described in more detail below – let us assume for now that the current carrying ion, say Na^+ , is equally distributed across the membrane and so only the potential difference across the cell membrane, the V_m , equates to the battery. At a typical resting V_m of around -80 mV, the cathode (or negative pole) is the intracellular solution and the anode the extracellular solution. The conductors are the membrane transport proteins (ion channels) that traverse the cell membrane. These channels have a central water filled pore that allows the ion to flow across the membrane, and generally also contain small molecular switches or gates that open or close this channel pore. The resistance of this circuit depends on the properties of these ion channels (how many ions they allow to pass) and how many of these ion channels are open in the cell membrane. When the channel gate is open, Na^+ ions flow into the cell causing a depolarization and activating some cell function (such as triggering an action potential or the release of a neurotransmitter).

In both the biological circuit and the hardwired circuit, the relationship between the potential difference (the battery, voltage, V), the amount of current (I) flowing through the circuit, and the resistance (R) or conductance (G) of the circuit is given by 'Ohm's law' (eqn [1]):

$$V = IR = I/G \quad [1]$$

From Ohm's law we can see that when current is injected into a typical cell, for example, by cations entering the cell from the external solution, the extent of the resultant depolarization produced depends on the resistance of the cell. The intracellular salt solution has a very low resistivity, so the cell's resistance depends on the amount of cell membrane, and the resistance of each unit of cell membrane. A cell membrane with a lot of open ion channels has a low resistance (or a high conductance, or is 'leaky') and will generate a smaller voltage change than that of a higher resistance cell in response to the same input of ionic current. Indeed, opening of ion channels to reduce a cell's input resistance and thereby reduce the voltage response to current injection is an important mechanism of inhibition in the brain ('shunting' inhibition; [Farrant and Kaila, 2007](#)). Given the same distribution of open ion

channels in a cell membrane, a larger cell will have a lower input resistance, and will require a greater input of ionic current to reach a specific V_m level. A physiological illustration of this is the 'size principle' for motoneuron recruitment during muscle contraction ([Henneman et al., 1965](#)). At modest levels of ionic current from afferent nerve drive, only the higher resistance smaller motoneurons are depolarized to the voltage threshold and activated. These small motoneurons innervate the 'slow-twitch' type muscle fibers that produce only modest muscle force. When stronger muscle contractions are needed, a greater afferent drive is needed to depolarize and activate the larger motoneurons that supply the fast twitch, high-force fibers. Hence by recruiting motoneurons in order of size and force, the brain can control the extent of motor force needed for a task (increasing force by increasing the frequency of activation is also important).

Ohm's law illustrates a very simple circuit with current flowing through a resistor driven by a voltage gradient. However, the cell membrane behaves like a resistor and a capacitor in parallel ([Figure 3](#)). A capacitor is an electrical device designed to store charge, and consists of two conducting plates separated by insulating material. The conducting plates are the salt solutions, and the insulating material is the lipid core. The lipid can support a different distribution of charges, or a different potential on each side. In a perfect capacitor, this charge separation would be maintained without decrement. However, the cell membrane contains ion channels that act as a resistor to allow the flow of charge (current) across the membrane. Therefore, the membrane is like a leaky capacitor. When charge is moved from one side to the other, via ionic current flow through open ion channels, the voltage on the two plates of the capacitor (the intracellular and extracellular surface) starts to change, but the change in V_m is not instantaneous. Current flows through the capacitive element of the circuit as the voltage across the capacitor changes. A new voltage difference is eventually established across the membrane, with an amplitude dependent on the membrane current, I_m , and the membrane resistance, R_m , as given by Ohm's law. Although the current is applied virtually instantaneously as ion channels rapidly open and close, the change in V_m changes with a membrane time constant (τ), given by the product of the resistance and capacitance of the circuit. [Figure 3](#) demonstrates the electrical circuit equivalent for a cell membrane, and the time course of a change in V_m when current flows into a cell.

Determinants of the Membrane Potential

The membrane potential (V_m) arises due to a different distribution of ions on each side of the membrane. One needs to understand two broad concepts to appreciate how this different distribution of ions can occur. Firstly, one needs to appreciate the forces that determine whether an ion moves in or out of the membrane. Secondly, there needs to be a means by which ions can move across the membrane – the membrane needs to be permeable to that ion. In this section we describe these two factors that determine the distribution of ions across the membrane, and thereby determine the V_m .

Figure 3 Electrical equivalent and voltage response of the cell membrane. (a) The lipid bilayer (right) acts like an ideal capacitor (left) that separates a charge, Q , on the two conducting plates, separated by a distance, d . The charge separation gives rise to a Voltage (V) across the capacitor (C), related by the equation $Q = CV$. The capacitance is directly proportional to the area of the plates, A , the dielectric constant of the medium, ϵ , the permittivity constant ϵ_0 , and inversely proportional to the distance between the plates ($C = Ae_0\epsilon/d$). (b) The membrane behaves electrically as an 'RC' circuit, an electrical circuit with a capacitor (from the lipid bilayer) and a resistance (from the ion channels) in parallel. Injection of a square pulse of current into this circuit (as may happen when an ion channel opens) gives rise to a slowly rising and decaying change in voltage as shown in the lower panel. The current rises to a value of $V = IR$ with a time course dependent on τ , the membrane time constant ($= RC$, or the time to decay to 37% of maximum, = the time to reach 63% of maximum). The voltage at time, t , during the rising phase is given by $V_t = IR \times (1 - e^{-t/\tau})$ while the voltage at any time, t , during the decay phase is given by $V_t = IR \times e^{-t/\tau}$. Electrochemical Driving Force for Ion Movement

The major ionic species inside and surrounding cells are K^+ , Na^+ , and Cl^- . Larger molecules that carry negative charges,

such as proteins and organic anions, and that find it difficult to cross the membrane form a pool of impermeant anions inside cells. Smaller concentrations of other ions such as bicarbonate, Ca^{2+} , inorganic phosphates ($H_2PO_4^-$, HPO_4^{2-}), and Mg^{2+}

Table 1 Physiological concentrations and equilibrium potentials of common physiological electrolytes

<i>Ion</i>	<i>Extracellular (mM)</i>	<i>Intracellular (mM)</i>	<i>E_{ion} (mV; 37 °C)</i>	<i>V_m–E_{ion} (mV)</i>	<i>Gradient at rest</i>
Na ⁺	145	18	+56	–132	Influx
K ⁺	3.0	135	–102	+26	Efflux
Ca ²⁺	1.2	10 ^{–7}	+125	–201	Influx
Cl [–]	120	7	–76	0	
HCO ₃ [–]	23	15	–11	–65	Efflux
pH [H ⁺]	7.4	7.2	–12	–64	Influx
Osmolality	290	290	Not applicable	Not applicable	Nil H ₂ O gradient

Note: Concentrations of Na⁺, K⁺, Ca²⁺, and Cl[–] are based on McCormick (2008); [HCO₃[–]] which was calculated using the Henderson–Hasselbalch equation (pH=6.1 + log [HCO₃[–]] – log (0.031 × PCO₂)) using the given pH values, and with CO₂=5% (PCO₂=38 mmHg). *E_{ion}* calculated for 37 °C using concentrations, assuming equal activities in both solutions. Resting *V_m* was taken as –76 mV, as measured for hippocampal neurons *in vivo* by Tyzio *et al.* (2008).

also exist in the extracellular and intracellular solutions. These ions do not exist in equal concentrations in these two solution compartments. Table 1 lists the brain concentrations of some physiological ions important in the context of membrane potentials. Cells use a significant amount of energy to actively transport or ‘pump’ ions across the membrane to establish these different concentrations. The Na⁺ pump, for example, hydrolyzes adenosine triphosphate (ATP) to pump Na⁺ ions out of the cell and to pump K⁺ ions into the cell (reviewed in Kaplan, 2002). The Na⁺ pump is one of the most important proteins in our bodies and found in virtually all polarized mammalian cells, where it creates a concentration gradient for K⁺ and Na⁺ across the cell membrane. The Law of Diffusion dictates that substances move from high to low concentrations, as the thermal motions of molecules give rise to collisions between closely spaced molecules that drives them further apart. Hence a chemical force exists for ions to move across the membrane from a high concentration to a low concentration. The chemical force acts to move K⁺ from the intracellular solution to the extracellular solution, and to move Na⁺ from extracellular to intracellular solution. However, as ions are charged substances, they are also subject to electrical forces. When placed in an electric field, a cation will be attracted to the negative pole and repelled from the positive pole, another Law of Physics – opposite charges attract and like charges repel. The cell membrane potential is an electric field across the membrane, and hence will also attract and repel ions from its positive and negative poles. The next paragraph examines how these two forces combine to produce a specific *V_m*.

Consider a hypothetical cell (Figure 4) in which the Na⁺ pump has established concentration gradients for Na⁺ and K⁺ across the cell membrane. This hypothetical cell is simplified by balancing the positive charge of these cations by including equimolar concentrations of Cl[–] on both sides. At hypothetical time=0 the membrane does not allow any ions to cross – it is impermeant to all the ions. The ionic charges are balanced in both the inside solution and outside solution (Figure 4(a(i))). Let us now make the membrane permeable to K⁺ by including open K⁺ – selective ion channels in the membrane. These channels we assume to be perfectly selective for K⁺, so the membrane remains impermeant to Cl[–] and Na⁺. The K⁺ ions will diffuse down their concentration gradient, from inside to out, carrying their positive charge as they move across the membrane. Their diffusion results in an excess

of K⁺ on the extracellular side of the membrane, and a deficit of K⁺ on the intracellular side. There exists an uneven distribution of charges, and hence the membrane is now polarized; negatively charged on the inside with respect to the extracellular side (Figure 4(a(ii))). This provides an electrical force on the ions. The negative *V_m* acts to attract the K⁺ toward the intracellular solution, countering the effects of the chemical force. An electrochemical equilibrium will be reached, where the chemical and electrical forces are equal, and the efflux of K⁺ due to the concentration gradient will be balanced by equal influx of K⁺ attracted by the negative *V_m*. The *V_m* at which this equilibrium is reached is called the equilibrium potential (*E_{ion}*) or Nernst potential. The Nernst equation (Box 2 below) equates the electrical and chemical forces that act on a specific ion, and is used to calculate the equilibrium potential for each specific ion (Table 1).

Relative Membrane Permeability

As shown in Table 1, the equilibrium potential for K⁺ under physiological ion concentrations in the brain and at body temperature is about –100 mV. Hence, if only highly selective K⁺ channels were open in a cell the *V_m* would rapidly equilibrate at –100 mV (Figure 4(b(i))). Imagine that (Figure 4(b(ii))) highly selective Na⁺ channels were opened instead of the K⁺ channels. Na⁺ would flow into the cell down its concentration gradient, causing an excess of positive Na⁺ inside the cell and a deficit outside the cell. The membrane would again become polarized with a positive *V_m*, that provides an electrical force to oppose the further influx of Na⁺. An electrochemical equilibrium would again be established, but this time at a positive *V_m*. The *V_m* would reach the equilibrium potential of Na⁺ which under typical physiological conditions would be about +60 mV (Table 1). Similarly, if a cell only allows Ca²⁺ or Cl[–] to move across the membrane the *V_m* would equal the equilibrium potentials of these ions, being +123 mV or –76 mV at the physiological concentrations of these ions (Table 1).

Imagine now (Figure 4(b(iii))) that a hypothetical cell was permeable to both K⁺ and Na⁺ (and no other ions) and contained physiological ion concentrations as in Table 1. K⁺ would leave the cell according to the chemical force, causing a negative *V_m*, and would continue to leave until the *V_m* reached the K⁺ equilibrium potential (*E_K*, –102 mV). At the same time, Na⁺ would enter, driving the *V_m* positive, and would

Figure 4 Electrochemical equilibrium and the resting membrane potential. (a) Schematic diagram illustrating how chemical and electrical forces combine to generate a membrane potential. In panel (i) (left) a hypothetical cell has a Na^+ pump that establishes concentration gradients for Na^+ and K^+ . In (ii) the cell becomes permeable to K^+ , which flows down its concentration gradient to establish the different ion charge distribution that is the membrane potential (V_m). (b) Hypothetical cells as in (a). In (i) only K^+ is permeable, K^+ flows out of the cell until the V_m reaches -102 mV , the equilibrium potential for K^+ (E_K). In (ii) only Na^+ is permeable, Na^+ flows in to the cell until the V_m reaches $+56 \text{ mV}$, E_{Na} . In (iii) both K^+ and Na^+ are permeable, with $P_K \gg P_{\text{Na}}$. K^+ flows out of the cell to drive V_m toward E_K , while Na^+ flows in to drive V_m toward E_{Na} . The V_m reaches a steady-state value somewhere in between, depending on the relative permeability toward K^+ and Na^+ . Neither ion is in equilibrium, so continue to flow down their electrochemical energy gradients, but the charge movement of Na^+ influx is balanced by that from K^+ efflux. This is similar to the resting V_m condition in many cells.

continue to enter until V_m reached the Na^+ equilibrium potential (E_{Na} , $+56 \text{ mV}$). The membrane potential would reach some steady-state value that balances these two opposing electrochemical driving forces. The exact value of the V_m would depend on the relative permeability of the membrane to K^+ and Na^+ . If the membrane was mostly permeable to K^+ ($P_K \gg P_{\text{Na}}$), the V_m would be closer to -100 mV ; if mostly permeable to Na^+ ($P_{\text{Na}} \gg P_K$) the V_m would be closer to $+60$. If the membrane was equally permeable to both K^+ and Na^+ ($P_K = P_{\text{Na}}$), the V_m would reach a steady-state value half way between E_K and E_{Na} (about -20 mV). Hence the V_m is a balance of the electrochemical driving forces for physiologically relevant ions, and the extent to which the membrane is permeable to each of these ions. This can be expressed mathematically using the Goldman-Hodgkin-Katz (GHK) equation (eqn [2]; Hodgkin and Katz, 1949). For further discussion of GHK and electrodiffusion equations applied to membrane potentials, see Hodgkin and Katz (1949), Keramidas *et al.* (2004), and/or Barry (2006). If the membrane is only permeable to a single ion, the GHK equation reduces to the Nernst equation.

$$V_m = RT/F \ln \left\{ \frac{P_{\text{Na}}[\text{Na}^+]_{\text{out}} + P_K[\text{K}^+]_{\text{out}} + P_{\text{Cl}}[\text{Cl}^-]_{\text{in}}}{P_{\text{Na}}[\text{Na}^+]_{\text{in}} + P_K[\text{K}^+]_{\text{in}} + P_{\text{Cl}}[\text{Cl}^-]_{\text{out}}} \right\} \quad [2]$$

$$V_m = RT/F \ln \left\{ \frac{[\text{Na}^+]_{\text{out}} + P_K/P_{\text{Na}}[\text{K}^+]_{\text{out}}}{[\text{Na}^+]_{\text{in}} + P_K/P_{\text{Na}}[\text{K}^+]_{\text{in}}} \right\} \quad [3]$$

$$V_m = RT/F \ln \left\{ \frac{[\text{Na}^+]_{\text{out}} + r.P_K/P_{\text{Na}}[\text{K}^+]_{\text{out}}}{[\text{Na}^+]_{\text{in}} + r.P_K/P_{\text{Na}}[\text{K}^+]_{\text{in}}} \right\} \quad [4]$$

Equations [2]–[4]. The GHK equation expressing the membrane potential (V_m) in terms of the permeabilities (P_x) for the most prevalent ions in physiological solutions (Na^+ , K^+ , and Cl^-). R , T , and F have their usual meaning and values as in Box 2. The subscripts in and out refer to intracellular and extracellular concentrations (or more correctly activities). The permeability constants give the velocity of ion movement through the membrane (cm per sec) and depend on the mobility and solubility of the ions in the membrane. P_{Na} , for example, $= RT/Fa \times v_{\text{Na}} \times K_{\text{Na}}$, where a = membrane thickness, v_{Na} = the mobility of the ion within the membrane, and K_{Na} is the partition coefficient between the membrane and aqueous solution. Assuming the membrane is only permeable to Na^+ and K^+ (a close approximation for a nerve axon) or that Cl^- is passively distributed (so $E_{\text{Cl}} = V_m$, example in some skeletal muscle fibers) then eqn [2] can be reduced to eqn [3] where P_{Na}/P_K is the relative Na^+ to K^+ permeability, a parameter that can be more readily

Box 2 Nernst potential and its derivation

The Nernst potential is derived considering the energy of ions inside and outside the cell at equilibrium – a special situation where there is no energy gradient between inside and outside. The free energy of a mole of ions includes components related to the chemical energy of the ion, the electrical energy acting on the ion and the standard energy on the ion in the absence of applied electrical or chemical energies, a property inherent to each ion species. This can be expressed as:

$$\mu_x = RT \ln[A_x] + zFV + \mu_o^X + PV_n$$

where μ_x = the free energy of the ion X, R = the gas constant (8.314 J K⁻¹ mol⁻¹, Joules per Kelvin per mole (as 1 V = 1 J C⁻¹, R can also be expressed in terms of VC per K⁻¹mol⁻¹)), T = temperature in Kelvins (K = °C + 273.15), A is the activity of ion X (which is related to molar concentration, C , by an activity coefficient, γ , specific for a particular salt solution: $A = \gamma \cdot C$), $\ln$ is the natural logarithm, z is the valency of the ion, F is Faraday's constant (96 485 C mol⁻¹, Coulombs per mole), V is the electrical potential (volts, or J C⁻¹), μ_o^X is the standard state potential for ion x, P is the hydrostatic pressure, and V_n is the volume of solution occupied by 1 mol of ions, the partial molar volume.

At equilibrium, the free energy of an ion on the outside will equal that of the ion on the inside of the cell so that:

$$\begin{aligned} \mu_{x \text{ outside}} &= \mu_{x \text{ inside}}; \text{ or} \\ (RT \ln[A_x] + zFV + \mu_o^X + PV_n)_{\text{outside}} \\ &= (RT \ln[A_x] + zFV + \mu_o^X + PV_n)_{\text{inside}} \end{aligned}$$

The standard state potential is the same inside and outside so can be deleted from both sides. The hydrostatic component is very small in animal cells (but can be large in plant cells) compared to the electrical and chemical forces on the ions (and is also roughly the same on both sides) so can also be eliminated from the equation. The activity coefficient for NaCl (0.75) is very similar to KCl (0.74) when the ionic strength of the intracellular and extracellular solutions are both at physiological values (~0.15 M; see, e.g., Barry *et al.*, 2013) and so can be eliminated from the equation and activity can be replaced by concentration.

So, after simplification and rearranging, our equation for the transmembrane ion energy difference at equilibrium becomes:

$$\begin{aligned} RT \ln[C_x]_{\text{outside}} - RT \ln[C_x]_{\text{inside}} &= zFV_{\text{inside}} - zFV_{\text{outside}} \text{ or} \\ zF(V_{\text{inside}} - V_{\text{outside}}) &= RT \ln[C_x]_{\text{outside}}/[C_x]_{\text{inside}} \text{ or} \\ zFV_m &= RT \ln[C_x]_o/[C_x]_i \end{aligned}$$

where V_m is the membrane potential defined as the inside potential relative to the outside potential, and the subscripts o and i refer to outside and inside, respectively.

This is the Nernst equation, where V_m is the membrane potential where ion X is at electrochemical equilibrium, often referred to as the Nernst potential or Equilibrium potential (E_x). In other words, V_m is the potential at which the chemical and electrical forces on an ion are exactly balanced.

experimentally measured. Equation [4] includes a coupling coefficient, r , to account for the contribution of the electrogenic Na⁺ pump (see text).

Steady State versus Electrochemical Equilibrium – the ‘Resting’ Membrane Potential

In most excitable or polarized cells (e.g., Figure 4(b(iii))), the resting V_m is about –70 mV, as the membrane permeability is dominated by K⁺ relative to other physiological electrolytes.

This high K⁺ permeability is due to most cells containing more open K⁺ channels (or ‘leak’ channels) at rest as compared to other types of ion channels. At a resting V_m of –70, neither K⁺ nor Na⁺ is at electrochemical equilibrium. For K⁺, the negative V_m that acts to attract K⁺ to the intracellular solution is insufficient to balance the chemical force driving K⁺ out. A relatively large number of open K⁺ channels combined with a small electrochemical driving force result in a continued small efflux of K⁺. For Na⁺, both the negative V_m and the concentration gradient provide a strong electrochemical driving force for Na⁺ influx. However, there are a relative small number of open Na⁺ channels and so only a small Na⁺ influx occurs. At rest when the V_m is not changing, we have a steady-state situation, in which the efflux of K⁺ is balanced by the influx of Na⁺. Changing the relative membrane permeability will disrupt this delicate balance. Opening of more K⁺ channels will allow K⁺ efflux to exceed Na⁺ influx and V_m becomes hyperpolarized. Conversely, closing some K⁺ channels, or opening of more Na⁺ channels, will result in less K⁺ efflux or more Na⁺ influx, respectively, and a depolarization of the V_m . Therefore by opening and closing K⁺ and/or Na⁺ channels, a cell can readily change its membrane potential. Cells also contain ion channels that allow other physiological ions such as Cl⁻, HCO₃⁻, and Ca²⁺ to diffuse across the membrane according to their electrochemical gradients. Hence by combining concentration gradients established by active transport mechanisms, and changes in relative membrane permeability by opening and closing an array of different types of ion channels, cells can change the V_m to a range of different levels and thereby induce and transduce physiologically relevant electrical signals. Such electrical signals include resting membrane potentials, action potentials, synaptic potentials, sensory, and receptor potentials.

Do Ion Concentrations Change When the V_m Changes?

A logical question to ask regards whether the efflux of K⁺ and influx of Na⁺ that occurs to establish the resting membrane potential changes the concentration gradients. Similarly with changes in V_m , such as action potentials and synaptic potentials, will these ion fluxes change the intracellular and extracellular ion concentrations? The answer is that only a relatively small number of ions flow across the membrane to generate the resting V_m or changes in V_m associated with action potentials or other membrane potential changes. The intracellular and extracellular concentrations do change, but for Na⁺ and K⁺ (and most other ions) this does not significantly change the concentration gradients. Box 3 below estimates that a single action potential in a typical nerve cell soma causes an increase in intracellular Na⁺ concentration of less than 1 μM, or <0.01% change from a resting concentration of about 18 mM. An even smaller relative change would occur with the efflux of K⁺ ions that generates the typical negative resting V_m . In a small diameter (1 μm) axon, a similar calculation gives a change of 0.2 mM Na⁺ during a single action potential. Prolonged high-frequency action potentials may elevate Na⁺ significantly in such small spaces (and some nerve axons or processes can be even thinner), although the Na⁺ pump is strongly stimulated by intracellular Na⁺ to counteract such buildup. During some pathological conditions such as seizures, the high frequency of action

Box 3 How many ions flow across the membrane to cause a voltage change of 100 mV?

An estimate of this can be done using some biophysical equations and approximated values. We consider the case of a neonatal rat motor neuron, for which we have reliable morphological and electrical data, with a somatic surface area of approximately $2 \times 10^{-5} \text{ cm}^2$ ($2000 \mu\text{m}^2$) and a total membrane capacitance of about 40 pF (Thurbon *et al.*, 1998).

$$\begin{aligned}\text{Charge (Q)} &= \text{Capacitance (Cm)} \times \text{Voltage (Vm)} \\ &= 40 \text{ p Farads} \times 100 \text{ mVolts} \\ &= 40 \times 10^{-12} \text{ F} \times 100 \times 10^{-3} \\ &= 4 \times 10^{-12} \text{ Coulombs (C; } 1 \text{ C} = 1 \text{ F.V.)}\end{aligned}$$

The charge on a single ion is the elementary charge, $1.6 \times 10^{-19} \text{ C}$. Hence $4 \times 10^{-12} \text{ C} = 4 \times 10^{-12} / 1.6 \times 10^{-19} = 2.5 \times 10^7$ ions.

1 mol of ions = 6.02×10^{23} ions (Avogadro's number) so 2.5×10^7 ions = 4.2×10^{-17} mol.

We will consider now that the charge carrier for the 100 mV V_m change is Na^+ , coming in to the neuron during an action potential. An efflux of K^+ to generate a -100 mV resting V_m would be the same charge movement, but would result in an even smaller relative change in the intracellular $[\text{K}^+]$ due to the higher resting $[\text{K}^+]$.

The surface area (SA) of a sphere is $4 \times \pi \times r^2$, the radius (r) is $\frac{1}{2} \times \sqrt{\text{SA}/\pi}$ while the volume is $\frac{4}{3} \times \pi \times r^3$. Assuming the soma equates to a sphere (an approximation), and neglecting the dendritic tree (for simplicity) the radius of the neuronal soma is:

$$\begin{aligned}\text{Radius} &= \frac{1}{2} \times \sqrt{\left[(2 \times 10^{-5} \text{ cm}^2) / \pi \right]} \\ &= 2.52 \times 10^{-3} \text{ cm (or } 25 \mu\text{m})\end{aligned}$$

$$\begin{aligned}\text{Volume} &= \frac{4}{3} \times \pi \times (2.52 \times 10^{-3} \text{ cm})^3 \\ &= 6.73 \times 10^{-8} \text{ cm}^3 \\ &= 6.73 \times 10^{-8} \text{ ml} \\ &= 6.73 \times 10^{-11} \text{ l}\end{aligned}$$

Hence a 100 mV action potential is an influx of 4.2×10^{-17} mol of Na^+ into a volume of 6.73×10^{-11} litres. Molar concentration is expressed as moles per litre, so:

$$\begin{aligned}&= 4.2 \times 10^{-17} \text{ mol} / 6.73 \times 10^{-11} \text{ l} \\ &= 0.62 \times 10^{-6} \text{ mol l}^{-1} \\ &= 0.62 \times 10^{-3} \text{ mmol l}^{-1} (\text{mM}) (\approx 0.0006 \text{ mM})\end{aligned}$$

Assuming an intracellular Na^+ concentration of 12 mM, a 0.0006 mM increase in Na^+ concentration is an increase of 0.005%, an insignificant change in total concentration.

potentials occurring synchronously in many neurons can also result in significant buildup of extracellular K^+ (Somjen, 2002). Usually extracellular K^+ increases will be buffered by surrounding glial cells or diffuse through the extracellular spaces, and saturation of this capacity can have detrimental effects such as helping to further propagate seizures and/or spreading depression (Somjen, 2002). Pathological changes in blood ion concentrations, often a result of kidney dysfunction or as a side effect of diuretics, can also result in changes in electrochemical driving forces and in the membrane potential. Chronic kidney disease, for example, is associated with hyperkalemia that results in chronic peripheral nerve depolarization and alterations in excitability that likely contributes to a range of uremic neuropathy symptoms (Krishnan and Kiernan, 2007).

Active Ion Transport via Primary and Secondary Active Transporters

For a specific ion to carry its charge across the membrane and change the membrane potential the membrane must be permeable to that ion. The membrane transporters that mediate movement of ions across the membrane fall into two broad categories: active and facilitated diffusion transporters (Table 2). Primary active transporters, such as the sodium pump ($\text{Na}^+/\text{K}^+/\text{ATPase}$) or the Ca^{2+} pump ($\text{Ca}^{2+}\text{-ATPase}$) directly utilize energy to establish ion concentration gradients. These gradients are used to fuel secondary active transport, in which the movement of one ion species down its electrochemical gradient is coupled to uphill movement of other ion species or solutes against their electrochemical gradient. These secondary transporters, such as the K^+/Cl^- cotransporter or the Na^+/H^+ exchanger, can also significantly influence the concentration gradients of ions that contribute to shaping the membrane potential. The K^+/Cl^- cotransporter and the $\text{Na}^+/\text{K}^+/\text{Cl}^-$ cotransporter are particularly important in determining Cl^- concentration gradients, as a primary active transport pump for Cl^- does not seem to exist in most cells. Some of these active transporters are 'electrogenic,' that is, they result in a separation of charge across the membrane in each transport cycle. The Na^+ pump, for example, exports 3 Na^+ ions and imports two K^+ ions in each transport cycle, utilizing one molecule of ATP in the process. Hence a net movement of 1 positive charge out of the cell occurs in each transport cycle resulting in an increase in negative voltage inside the cell. Blocking the Na^+ pump using ouabain has been reported to depolarize the V_m by 2–3 mV, as well as resulting in a gradual build up of intracellular Na^+ and depletion of intracellular K^+ (e.g., Thomas, 1972). The modest effects on V_m of the Na^+ pump as compared to ion channels relate to the 1000-fold or more lower rates of ion transport through the Na^+ pump (and other active transporters) as compared to ion channels. Hence their contribution to relative membrane permeability is also minimal. The Na^+ pump undergoes numerous conformational changes during the transport cycle, binding and trapping Na^+ and K^+ and undergoing phosphorylation and dephosphorylation in a series of discrete conformation states. Even when the Na^+ pump is strongly stimulated, the rate at which it moves Na^+ or K^+ across the membrane is of the order of 10^3 – 10^4 ions per second, whereas ion channels can mediate ionic fluxes of at rates of 10^6 – 10^8 ions per second (Hille, 1992). The small contribution that the electrogenic Na^+ pump contributes to the resting membrane potential can be accounted for by modifying the relative Na^+ and K^+ permeability using a coupling coefficient, the parameter r in eqn [4] (Mullins and Noda, 1963). This coefficient reflects the pumps transport stoichiometry, being 3/2 for the Na^+ pump. Using physiological values of Na^+ and K^+ concentrations and relative permeabilities, eqn [4] calculates that the Na^+ pump contributes a 2.0 mV hyperpolarization to the resting membrane potential.

Passive Ion Transport via Selective, Facilitated Diffusion Ion Channels

Although primary and secondary active transporters establish and maintain ion gradients, ion channels, being facilitated

Table 2 Classification and distinguishing characteristics of membrane transport processes

	Passive processes			Active processes		
	Facilitated diffusion			Primary active transport		
	Carrier	Channel		Co-transport	Counter transport	
Alternate name	Lipid diffusion	Diffusion carrier	Channels or pores	Pump	Uniporter	Exchanger
Energy used	Nil	Nil	Nil	Yes, direct	Yes, indirect	Yes, indirect
Chemical nature of transported substance	Nonpolar/lipid soluble molecules	Ions or other polar substances	Ions or other polar substances	Ions or other polar substances	Ions or other polar substances	Ions or other polar substances
Permeation pathway/mechanism	Via the lipid	Via membrane protein	Via membrane protein	Via membrane protein	Via membrane protein	Via membrane protein
Driving force for solute movement	Chemical (concentration gradient)	Chemical (concentration gradient)	Electrochemical (concentration gradient and electrical force)	ATP hydrolysis fuels uphill solute flux	Solute movement down electrochemical gradient drives another solute uphill in same direction	Solute movement down electrochemical gradient drives another solute uphill in opposite direction
Example of substances transported	O ₂ , CO ₂ , steroids	Glucose, amino acids	Na ⁺ , K ⁺ , Cl ⁻ , Ca ²⁺ , H ₂ O	Na ⁺ , K ⁺ , Ca ²⁺ , H ⁺	Glucose, amino acids, Cl ⁻	Ca ²⁺ , H ⁺
Example of transporter	Not applicable	GLUT4 glucose transporter	Voltage-dependent Na ⁺ channel	Na ⁺ /K ⁺ /ATPase (Na ⁺ pump)	GLUT1 glucose transporter	Na ⁺ /Ca ²⁺ exchanger
Example of physiological function	Oxygen flow from blood to cells	Glucose movement into cells following a meal	Generation and propagation of the action potential	Establish and maintain physiological [Na ⁺] and [K ⁺]	Store glucose into liver cells	Intracellular [Ca ²⁺] homeostasis

diffusion transporters, dissipate these ionic gradients. The study of ion channels has been remarkably advanced over the past two decades by the elucidation of the crystal structure of ion channels from bacteria and other simple organisms which can be grown to yield large quantities of membrane proteins amenable to crystallization. These ion channels have gene sequences and protein structures homologous to our own ion channels, so provide insights into mammalian ion channels. The importance of this work was recognized by the award of the Nobel Prize in chemistry in 2002, to Professors Rod Mackinnon and Peter Agre for their discoveries concerning K^+ channels and water channels, respectively (see Relevant Websites). The structure of the yeast KcsA K^+ channel discovered by Prof Mackinnon's laboratory in 1998 is shown in Figure 5 (a) (Doyle *et al.*, 1998). It illustrates some of the key structural features of ion channels – a 'selectivity filter' that allows certain ions to pass into the aqueous channel pore but not others, and a 'channel gate' that opens and/or closes in response to certain stimuli and thereby allows different changes in membrane permeability under different physiological conditions.

The selectivity properties of K^+ channels such as the KcsA channel are quite remarkable – they can allow K^+ ions to pass through at high rates of up to $1 \text{ million sec}^{-1}$ while the very similar and slightly smaller (when dehydrated) Na^+ ion is strongly excluded (the $K^+ : Na^+$ selectivity of some K^+ channels is 100:1 or more; Hille, 1992; Doyle *et al.*, 1998). Such high selectivity can be achieved as the dehydrated K^+ ion fits perfectly into the somewhat rigid selectivity filter, where it can be momentarily stabilized by interactions with negative dipoles from carbonyl oxygen groups arising from some of the amino acids that form the selectivity filter (Figure 5(b)). The energy lost by liberating the hydrating H_2O molecules can be regained by interactions with the carbonyl oxygens. Na^+ ions, in contrast, cannot interact as closely with the negative dipoles in the selectivity filter (the diameter of a bare Na^+ is slightly smaller than K^+ – 0.09 nm compared to 0.10 nm) and hence prefers to stay hydrated by H_2O . An important principle of relative ion selectivity is this balance between energy of dehydration and energy of interaction with residues within the selectivity filter. Voltage-dependent Na^+ , K^+ , and Ca^{2+} channels are, in general, very highly selective, but other channels have lower selectivity. The synaptic glutamate and acetylcholine receptors can pass both Ca^{2+} , Na^+ , and K^+ to various degrees amongst the different subtypes. Nicotinic acetylcholine channels in frog skeletal muscles do not discriminate much amongst monovalent cations and have a relative $Ca^{2+} : Na^+$ permeability of about 0.2 (Adams *et al.*, 1980) while the neuronal $\alpha 7$ subtype is more permeable to Ca^{2+} than Na^+ by about 10:1 (Bertrand *et al.*, 1993). Anion channels, such as gamma-aminobutyric acid (GABA) and glycine-receptor channels, are generally also weakly selective amongst different anions, and can even let a small degree of cations to pass through (Keramidas *et al.*, 2004; Franciolini and Nonner, 1987; Sugiharto *et al.*, 2008). Note in the KcsA channel the negatively charged residues surrounding the entrance to the channel pore. This illustrates another common theme in ion channel permeation – charged residues surrounding the entrances to the channel pore can concentrate permeant ions and hence increase the rate at which they can then flow through the channel pore (Moorhouse *et al.*, 2002; Carland *et al.*, 2009). These charged residues may also

Figure 5 Structure of a K^+ -selective ion channel. (a) X-ray structure of the bacteria *Streptomyces lividans* KcsA K^+ channel (Doyle *et al.*, 1998). Two adjacent polypeptide subunits (of the four in total) are shown. The two transmembrane alpha-helical segments, and the angled pore-helix, are indicated in blue, some other amino acids are numbered and labeled with their single letter code. Of note is the 'GYG pore selectivity filter' that lines the top of the channel pore, and the 'channel gate' at the intracellular end. Adapted with permission from part of Figure 4 of Doyle, D.A., Morais, C.J., Pfuetzner, R.A., *et al.*, 1998. The structure of the potassium channel: Molecular basis of K^+ conduction and selectivity. *Science* 280, 69–77. (b) Schematic diagram illustrating energetics of why the larger diameter K^+ ion is selected over the smaller diameter Na^+ ion in the pore of the KcsA K^+ channel (panels C–F of Armstrong, C., 1998. *Science* 280 (5360), 56–57, with permission). Both ions are hydrated and stable when in the extracellular and intracellular solutions (and also in the central cavity of the channel). However, in the restricted region of the selectivity filter, the ions need to be dehydrated to pass through, K^+ 'fits' better in the selectivity filter of Na^+ , as it can be more effectively stabilized by the negative dipole of carbonyl oxygens from the pore structure.

contribute more directly to determining which type of ion – an anion or cation – is preferred through the pore (Keramidas *et al.*, 2002; Cymes and Grosman, 2012).

Ion Channel Gating

Figure 5(a) also illustrates the occlusion of the aqueous pore that forms the channel gate. The KcSA structure in Figure 5(a) represents a nonconducting state through which no ions can pass. A decrease in the pH of the bacteria cell induces conformational changes that include large opening at the inner end of the membrane domains and that ultimately results in a conducting channel (Liu *et al.*, 2001). For voltage-dependent channels, membrane potential changes are detected by specialized voltage-sensor domains that respond with conformational changes that initiate opening of the channel pore (Bezaniilla, 2000). In the cys-loop family of ligand-gated ion channels, the channel gate lies within the transmembrane pore that is more than 50 Å away from the specific ligand-binding domain – yet when the neurotransmitters bind to this site, a conformational wave is initiated that opens the channel in less than 0.1 ms (Sine and Engel, 2006). Membrane stretch is another way of activating channels, as well as being able to change the sensitivity of channels to other forms of gating. Other channels are ‘leaky,’ or open in absence of any particular stimuli. These channels include the K^+ selective channels referred to above in the context of setting the resting membrane potential. Ion channels, however, do not spend all their time in just one conformational state and may spontaneously switch between closed and open conformations. Some resting ‘leak’ channels, for example, the inward rectifying K^+ channels can be gated to either increase or decrease the amount of time spent in the open conformation: binding of G-protein subunits can open channels of the Kir gene family 3, while K^+ channels of the Kir family 6 decrease their open time when ATP levels in cells increase (Reimann and Ashcroft, 1999). Furthermore, channels have multiple gates – voltage-dependent channels, for example, activate in response to a depolarization and then inactivate during sustained depolarization via a second distinct ‘inactivation’ gate that occludes the open pore. This fast inactivation process is important for rapid electrical signaling; toxins or genetic mutations that disrupt the inactivation gate of voltage-dependent Na^+ or Cl^- channels can result in muscle diseases and epilepsy (Ashcroft, 2000). In an analogous fashion, some ligand activated channels can also transit to a closed conformation in the sustained presence of ligand through a process known as ‘desensitization.’ The precise nature of this desensitization gate remains unknown. Clearly the modes and mechanisms of channel gating are numerous and complex, yet enables changes in membrane permeability at different times in response to different physiological stimuli that result in a myriad of membrane potential changes such as action potentials, synaptic potentials, sensory potentials, and more.

Passive Membrane Potential Changes

The membrane potential changes underlying an action potential, generated in response to sensory stimulation, or arising in response to release of neurotransmitters at a synapse, all involve ionic currents flowing across the membrane through different

ion channels. Membrane potential changes can also occur in the absence of a specific activating stimulus, but rather arise ‘passively’ (although ions also flow passively through channels) or ‘electrotonically’ by conduction between two regions of different potential within the cell. A geometrically simple cell, such as a small and round neuron without much processes, or a red blood cell, is isopotential, meaning that the membrane potential at each point inside the cell is the same. For cells of more complex geometry, such as an elongated muscle cell, a long nerve axon, or a nerve cell with extensive dendritic elongations, the V_m at one point of the cell can differ from that at other points of the cell. Consider a motoneuron innervating a muscle in the foot: an action potential depolarizes the soma membrane within the ventral horn of the spinal cord, but the neurotransmitter that initiates the muscle response is packaged in a nerve terminal up to 1 m away. When the soma is depolarized by the action potential, the V_m at the nerve terminal is still at rest, and the depolarization needs to spread along the nerve cell to the terminal to initiate neurotransmission. Similarly, a layer V pyramidal neuron gets depolarized at a distal synapse in a different layer of the cortex, and this V_m change needs to spread to the soma where an action potential response could potentially result. In both these cases, the V_m is not the same at these two points in the same cell, creating a potential difference between these two points that drives the movement of charge, or current. Cations will flow along the core of the dendrite or axon from the depolarized region to the more hyperpolarized region (with anions flowing in the opposite direction). As the positive current moves along the cell membrane, it causes a spread of depolarization. This local current flow is ‘passive’ or ‘electrotonic’ propagation, and works just as effectively for the spread of either depolarizations or hyperpolarizations. The distance and speed at which this passive depolarization (or hyperpolarization) is propagated along a cell membrane depends on (1) the amplitude of the difference in potential between the two points, (2) how many ions will ‘leak’ out across the plasma membrane, relative to how many will flow through the core of the axon, dendrite, or other excitable cell, and (3) how quickly will this movement of charge causes a change in the V_m . Figure 6 demonstrates the decay of these passive responses as one gets further away from the point at which the membrane is most polarized. Figure 3 demonstrates how the passive response recorded at a single point in response to a step change in current changes over time. The two key intrinsic or passive properties of the cell membrane that control these temporal and spatial aspects of the membrane potential are the ‘space constant’ and ‘time constant’ – and these can vary markedly across cells of different shapes and sizes. A series of cable equations relate the resistances, capacitances, and geometries of the membrane and interior of a nerve ‘cable’ to the distance and speed a passive propagation can travel (Figure 6; see also Aidley, 1989; Boron and Boulpaep, 2009; Byrne, 2015). Over short distances of less than 1 mm, from the membrane of a synaptic cleft to the extrasynaptic membrane in a skeletal muscle, or from one Node of Ranvier to another in a myelinated nerve axon, passive depolarizations can be effective. But they will not suffice to propagate a depolarization in a long motoneuron nor even in a long dendritic tree. For long distance spread of membrane potentials, active depolarizations are required. In nerve axons, local (passive) currents spread the depolarization to an adjacent region

Figure 6 Passive membrane properties of a cylindrical cell. (a) Schematic diagram of a nerve axon, indicating the equivalent electrical properties of axoplasmic or internal resistance, r_i , an external resistance (r_o), a membrane resistance (r_m), and membrane capacitance (c_m) (see also Figure 3). These values defined for a unit length of a cylinder or cable can be converted to those of a unit area by incorporating the axon radius, a , so that $r_i = R_i/\pi a^2$ ($\Omega \text{ cm}^{-2}$), $r_m = R_m/2\pi a$ ($\Omega \text{ cm}^{-2}$), and $c_m = C_m \times 2\pi a$ ($\mu\text{F cm}^{-2}$). (b) As ionic current is injected into a particular point along a cylindrical cell via a microelectrode (or via the opening of an ion channel) the current passively spreads laterally. As the cell membrane is an imperfect insulator, some of the current that was injected 'leaks' across the membrane, meaning that less and less current is available to continue to spread along the axon. (c) A consequence of this leak of current is that the voltage response, or V_m , exponentially decreases in magnitude as distance from the source of the current increases. The decay depends on the amount of current that stays inside the fibre (or does not leak out), which depends directly on r_m and inversely on the sum of r_i and r_o . One can define a parameter, the space constant, λ as $\lambda = \sqrt{(r_m/r_o + r_i)}$, and show (e.g., Aidley, 1989, p. 37) that this equals the distance over which the response decays to 37% of its original or peak value (V_o). The voltage at distance x , $V = V_o e^{-x/\lambda}$. As $r_o \ll r_i$, one can simplify as $\lambda = \sqrt{(r_m/r_i)}$. For a unit area of axon, $\lambda = \sqrt{(aR_m/2r_i)}$; and hence λ increases as axon diameter increases (see Aidley, 1989, p. 38). This is particularly important for the propagation of the action potential along an axon, as the conduction velocity is directly proportional to the λ (and inversely proportional to the time constant τ , the product of $R_m \times C_m$). Reproduced from Figure 7.22 in Boron, W.F., Boulpaep, E.L., 2009. Medical Physiology. A Cellular and Molecular Approach, second ed. Philadelphia, PA: Saunders Elsevier. © 2002 Elsevier Science, USA.

where the depolarization crosses a threshold and activates the voltage-dependent Na^+ and K^+ channels to regenerate the action potential (that again spreads passively to the next region to be regenerated and so on).

Measuring Membrane Potential and Relative Membrane Permeability

Direct Measurements of Membrane Potential and Membrane Selectivity

The membrane potential is directly measured by inserting an electrode into the inside of a cell and recording the potential

difference between this electrode and one in contact with the solution outside the cell. This was first done for nerve cells by Hodgkin and Huxley (1939) who lowered a wire inside the giant axon of the squid, *Loligo forbesi*, to 1st observe the nerve membrane potential both at rest and in response to stimulation. The experimental approach is shown in a lovely video produced at the Marine Biology Laboratory in the 1970s and posted on youtube (see Section Relevant Websites). A more complete description of this experimental approach and the results was subsequently published in the *Journal of Physiology* (Hodgkin and Huxley, 1945) and is illustrated in Figure 7. The resting V_m of about -50 mV became positive (about $+40 \text{ mV}$) during

Figure 7 Direct recording of a nerve membrane potential using an intracellular microelectrode. (a) Photomicrograph of portion of the isolated giant axon of the squid, *Loligo forbesi*, with a 20 μm silver wire enclosed within a ≈100 μm glass capillary that is visible inside the ≈0.5 mm fibre (each small division represents 33 μm). (b) Direct recording of the V_m using the configuration shown in (a). The potential difference is between the silver wire microelectrode and a ground electrode connected to the seawater outside the nerve. The y axis is in mV, the time marker is cycles at 500 Hz (or 1 peak per 2 ms). Reproduced with permission from panel a, Plate 1 and Plate 2 of Hodgkin, A.L., Huxley, A.F., 1945. Resting and action potentials in single nerve fibres. *Journal of Physiology* 104, 176–195.

the action potential – this observation that the V_m overshoot zero revealed important insights into the mechanisms of the action potential. Their subsequent application of the voltage-clamp technique, coupled with rigorous and thoughtful analysis, elucidated the basic biophysical mechanisms of the resting and action potential in nerve axons. They provided a highly influential quantitative description of the membrane potential

changes in terms of changes in the membrane conductances to Na^+ and K^+ , and the relative membrane permeabilities of the membrane to these ions. On the 50th anniversary of the publication of a series of five seminal papers in the *Journal of Physiology* (1952), a special celebratory issue was published that describes the impact and legacy of their contribution (see Section Relevant Websites).

Using this intracellular recording wire electrode and squid axons, Hodgkin and Katz (1949; also analyzing earlier data of Curtis and Cole) investigated how the resting V_m and the peak amplitude of the action potential varied as a function of external K^+ and Na^+ . They demonstrated that the resting V_m was sensitive to K^+ changes but not Na^+ changes, and vice versa for the V_m at the peak of the action potential. Fitting the data to the GHK equation gave relative permeabilities, $P_{\text{K}}/P_{\text{Na}}$, of about 25:1 for the resting V_m , and about 1:20 for the peak of the action potential. However, mammalian cells are much smaller than these giant squid axons and not amenable to insertion of a fine wire. Using instead a sharp glass microelectrode (with a tip of <0.1 μm), Hodgkin and Horowitz (1959) conducted similar experiment on isolated skeletal muscle fibers of the frog, measuring resting V_m and changing the external K^+ , Na^+ , and Cl^- concentration in various combinations. The resting V_m was similarly highly dependent on external K^+ , with a linear relationship over most of the concentration ranges tested, but with a clear deviation from this relationship at lower extracellular K^+ (see their data in Figure 8). This deviation is consistent with the membrane being not only permeable to just K^+ , and fitting the data to the GHK equation gave a $P_{\text{Na}}/P_{\text{K}}$ of 0.01 for the resting V_m (Figure 8). When the external $[\text{K}^+]$ is low, the V_m is very hyperpolarized so that the electrochemical gradient for Na^+ influx is very strong (while that for K^+ is very weak), and the deviation occurs because we now see a significant effect of the Na^+ influx on V_m , despite the low relative Na^+ permeability. This work also appreciated (and quantified) that muscle had a high resting Cl^- conductance and permeability, but that the steady-state V_m was independent of changes in $[\text{Cl}^-]_o$ (Hodgkin and Horowitz, 1959). This seeming contradiction arises because Cl^- is not actively transported across the membrane of skeletal muscle and therefore distributes its concentration gradient passively with V_m so that $E_{\text{Cl}} = V_m$. When muscle V_m changes, the high Cl^- conductance of muscle plays an important role in reducing the extent of V_m changes and stabilizing muscle excitability. During an action potential, for example, Cl^- influx into the depolarized muscle is important for repolarization. Indeed, recessive or dominant mutations in the major human skeletal muscle Cl^- channel (CLC1) can cause severe muscle diseases known as generalized myotonia (Becker's disease) and myotonia congenita (Thomsen's disease), respectively (Ashcroft, 2000).

Quantifying Membrane and Ion Channel Selectivity Using Voltage-Clamp

In neurons, where active transporters for Cl^- typically exist (e.g., KCC2 and NKCC1), K^+ , Na^+ , and Cl^- (and to some extent other ions such as Ca^{2+} and HCO_3^-) all contribute to the V_m . The extent to which they do so varies considerably – as the membrane permeability to these ions is constantly

Figure 8 Quantifying the relative permeability of the cell membrane at rest. Direct recording of the resting V_m of frog skeletal muscle using an intracellular microelectrode, and the dependence of this resting V_m on the concentration of K^+ in the external solution. The experimental data points at different times after solution change (and/or after decreases and increases in K^+) are given by the open circles and crosses. This data is fit by the Nernst equation (right straight line) and by the GHK equation (left curved line). The better fit is obtained with the GHK equation assuming a relative $P_{Na}:P_K$ value of 0.01. Reproduced with permission from Figure 5 of Hodgkin, A.L., Horowicz, P., 1959. The influence of potassium and chloride ions on the membrane potential of single muscle fibres. *Journal of Physiology* 148, 127–160.

changing. Knowing what ion channels are opened by different stimuli, and the ion selectivity properties of these channels – that together determines the membrane permeability – is an important aspect of understanding and predicting the different types of membrane potential changes seen *in vivo*. Measuring the ionic selectivity of a specific ion channel, or of the membrane as a whole, involves the same basic experimental approach as illustrated by the early recordings of Hodgkin, Huxley, and their contemporaries – changing the external solutions and measuring the V_m . However, this is more precisely done using the voltage-clamp technique. Direct V_m measurements can be complicated by the fact that changes in the membrane potential can themselves change the channels that are open or the driving forces for ion movement. Greater experimental control is achieved using voltage-clamp recordings – an experimental approach where one controls the voltage by using a feedback amplifier to inject positive or negative current into the cell. The experimenter therefore controls the voltage and measures the current flowing through any channels open at that voltage. To apply to selectivity measurements, one first records the voltage at which no ionic currents flow across the membrane, the current reversal potential (V_{rev}), and then changes the solutions on one side of the membrane, and measures the new V_{rev} . The V_{rev} is the voltage where the ionic currents are at equilibrium. With knowledge of the ionic composition of the solutions, one can calculate the relative permeability of the membrane using the GHK equation as described above. If a single ion channel is responsible for the

current being measured (either because it has been over-expressed in a cultured cell, or because it has been selectively activated), then these relative permeability measurements correspond to the selectivity properties of the channel itself. Good solution and voltage control, and accounting for various voltage offsets inherent in these recordings (such as liquid junction potentials) is needed to accurately quantify membrane or channel selectivity. Using ionic activities (rather than concentrations) is particularly important when the control and test solutions have different ionic strengths, such as in dilution potential experiments often used to quantify selectivity. The procedures to accurately measure and quantify membrane selectivity are described in more detail elsewhere (Barry, 2006; Sugiharto *et al.*, 2008; 2010; Moorhouse *et al.*, *in press*), and the results from such an experiment are illustrated in Figure 9.

Caveats in Measuring Physiological V_m

Use of a microelectrode or patch clamp pipette to measure the potential difference between electrodes inside and outside of the cell is a direct and simple way to measure the membrane potential, but is associated with a number of limitations. Inserting a sharp microelectrode through the cell membrane causes some damage or holes through the membrane. These holes are nonselective ‘leak’ conductances that will change the composition of the cell and thereby potentially affect V_m . In hippocampal neurons, this damage-induced leak

Figure 9 Quantifying ion channel selectivity using whole-cell patch clamp recordings. (a) Schematic diagram of the whole-cell patch clamp recording that allows the cell to be perfused with an intracellular solution of known ionic concentration, in this case largely 150 mM NaCl. The external solution can also be controlled, and changed from a symmetrical 150 mM NaCl (upper) to a 25% diluted solution (containing 38 mM NaCl; lower). The cell can also be voltage-clamped by the patch clamp configuration, allowing the experimenter to control the V_m and record the currents flowing across the membrane. (b) Example of glycine-receptor activated ionic currents recorded at different membrane potentials using whole-cell configuration as in (a), in symmetrical (upper) and in 25% dilution NaCl solutions (lower). The inserts show ionic currents in the presence of glycine, at different V_m s. The graphs plot these V_m s vs. current, I - V , relationships with the averaged V_m at which the current was zero (V_{rev} s) shown in the two graphs. (c) The averaged shift in V_{rev} as external NaCl is diluted to 50% and then 25% across six different cells is plotted against the external Cl activity, and fit with the GHK equation to obtain a P_{Cl}/P_{Na} value of about 12 for the recombinant human $\alpha 1$ glycine receptor. For further detail see Sugiharto *et al.* (2010). As the external NaCl is diluted, a chemical gradient is created for efflux of both Na^+ and Cl^- . As the GlyR is more permeant to Cl^- , a positive V_m is needed to counterbalance this chemical force, and hence V_{rev} shifts to positive values. A negative shift is seen if $P_{Na} > P_{Cl}$. Panels (b) and (c) have been published in different formats as parts of Figures 1 and 2 in Sugiharto *et al.* (2010).

causes the subsequent activation of ion channel conductances that reverse near the resting V_m , hence the cell's resting input resistance is changed, but there is not so much change in the resting V_m (Staley *et al.*, 1992; Spruston and Johnston, 1992). This damage is minimized with patch clamp recordings in which the membrane is sealed against a glass pipette, rather than the membrane pierced by the pipette. The resting cell input resistance (a measure of such 'leak') is 3–10-fold higher when the same neuron is recorded using patch clamp electrodes as compared to sharp microelectrodes (Staley *et al.*, 1992; Spruston and Johnston, 1992). So in this respect, a more physiological V_m value could be obtained with patch clamp recordings. A caveat with both patch clamp and sharp

microelectrodes is that ions leaking from the recording pipette into the cell will change the intracellular ionic composition and hence the physiological V_m . While this is much more significant for large patch clamp electrodes *cf* sharp microelectrodes, it can be better defined with patch electrodes. Indeed in standard whole-cell patch clamp recordings, the cell interior is almost completely (with time) dialysed by the pipette solution, so one can try to replicate the ionic concentrations and include other constituents to match the physiological milieu as close as possible. Perforated patch clamp recordings can maintain more closely the physiological ion concentrations. This variant of patch clamp recording typically uses different antibiotics inside the pipette solution that forms membrane pores with

permeability limited to ions within a restricted size or polarity, thereby enabling electrical continuity with the intracellular solution while maintaining the physiologically relevant signaling molecules and other larger constituents (Ishibashi *et al.*, 2012). Gramicidin perforated patch, for example, are impermeable to anions and hence have been useful for recording physiological responses to Cl-selective ion channels such as GABA and glycine-activated receptor-channels. While perforated patch can reduce inaccuracies in measuring physiological V_m related to disrupted intracellular cytoplasm, the technique is associated with a poorly defined voltage offset, relating to the fact that the larger charged molecules left inside the cell may not be properly balanced by charges inside the pipette solution (Horn and Marty, 1988). The liquid junction potential arising from the interface between pipette and bath solutions during the patch clamp procedure, that is between 3–8 mV with typical experimental solutions, must also be taken into account (Barry and Lynch, 1991). Furthermore, one must also appreciate that the voltage-clamp technique can only accurately control the membrane voltage of the membrane isopotential with the pipette – such as the soma in a neuron, while distal regions of cells with complex geometry – such as neuronal dendrites – are less-well controlled, particularly when the voltage or currents across the membrane are rapidly changing (Spruston *et al.*, 1993). Finally, much of our data on membrane potentials comes from *in vitro* conditions where tissues are more readily accessible and solutions and voltage more easily controlled, one must also appreciate that this situation may be quite different from *in vivo* recordings. Indeed, the V_m fluctuates much more widely in *in vivo* conditions, with much more influences of synaptic and neural circuit activity.

Physiological Values of V_m

Despite the caveats above, one should not be discouraged from measuring directly V_m using electrophysiological approaches – it is after all a necessary step in quantifying and understanding brain and body function and mechanisms. Using electrophysiological approaches, a wide range of resting V_m values have been reported for neurons (Table 3). Some of this variability may be technical: for example, Tyzio *et al.* (2003) have demonstrated that in small-sized neurons, a lower resistance pipette-neuron seal, and the procedure of going whole-cell can both depolarize the V_m somewhat. Avoiding this using a cell-attached variant gave a resting V_m of about -77 mV, both *in vitro* and *in vivo* (Tyzio *et al.*, 2003, 2008). However, even more hyperpolarized resting V_m have been reported using standard patch clamp recordings, suggesting minimal artifactual depolarizations in these studies (Table 3). Table 3 is populated with studies where V_m has been recorded in the same conditions but for different experimental techniques. A number of noteworthy points are: (1) the V_m can vary markedly in different cell types, both *in vitro* and *in vivo* (e.g., 15 mV difference in averaged V_m of mitral cells and granule cells within the olfactory bulb), (2) there seems little effect of age and preparation type when V_m is recorded using the same conditions (e.g., Tyzio *et al.* papers report approximately the same V_m value in slices, in culture, *in vivo*, and across development), and (3) the results reported by different groups using the same preparation can vary. The variability seems particularly large *in vivo*, perhaps not surprising considering the large spontaneous V_m fluctuations reported. In the somatosensory

Table 3 Some reported resting neuronal V_m values, recorded under different conditions to illustrate potential sources of variability

Neuron type	Preparation	Technique	V_m	Reference
<i>In vitro</i>				
Hippocampus DG ^a	Brain slice	WC ^c patch clamp	-84 ± 1.0 (31)	Staley <i>et al.</i> (1992)

cortex of the awake, behaving mouse, the 'resting' V_m oscillates at a frequency of 1–5 Hz and with an amplitude of up to 20 mV (Poulet and Petersen, 2008; Gentet *et al.*, 2010). During active behaviors, such as whisking, the V_m oscillations in corresponding cortical neurons are reduced and the baseline V_m becomes a few mV more depolarized (Poulet and Petersen, 2008). Averaging the V_m fluctuations over a few seconds gives values of -60 mV to -50 mV, but the exact value depends very much on the oscillation frequency and the brain state when recordings are measured. Furthermore, the frequency and amplitude of the currents responsible for these oscillations are markedly affected by different anesthetics (Doi *et al.*, 2007). Indeed, the concept of a 'resting V_m ' is perhaps meaningless for some types of neurons *in vivo*, highlighting the dynamic nature of neuronal activity that can be obscured *in vitro*.

In summary, one cannot give a uniform and single answer to 'What is the resting V_m ?' In neurons, it may be as depolarized as -50 mV, and as hyperpolarized as -85 mV. In less dynamic and more homogeneous cell types, it may be more consistent. *In vivo*, V_m may never be 'resting.' Clearly it depends on the region examined, but can also be affected by the recording approach. With careful consideration of voltage offsets, solutions and other potential caveats described above, measurements can provide good estimates of physiological V_m . While caution is needed in comparing across different conditions, changes in V_m induced by some physiological or experimental manipulation can be quite valid and informative.

Conclusion

This article provides an overview of the membrane potential – the polarization of cell membranes arising from a different distribution of ionic charges between the intracellular and extracellular surface of the cell membrane. Some physical and chemical properties of the ions and the membrane were introduced. The lipid nature of the membrane provides an energetically high barrier to passage of hydrated ions, making it a good separator of charge. Active transporters use energy, directly or indirectly, to establish ion concentration gradients and to move ions and other solutes against their energy gradients. Ions can rapidly cross the membrane via ion channels that contain integral membrane pores allowing ions to move passively down their electrochemical gradients. Ion channels have selectivity filters that control the flow of ions across the membrane, and gates that can be opened and closed in response to different physiological stimuli. The nature and number of ion channels open gives rise to the selectivity of the membrane for particular ions, and it is the combination of the relative membrane selectivity to different ions and the electrochemical driving force for each ion that sets the membrane potential at any particular time. Quantifying the relative selectivity of the membrane, or of individual channels, is a key component of understanding the molecular and cellular mechanisms of membrane potentials – this can be readily undertaken but one must be aware of various caveats and offsets involved in such measurements. Similarly, careful consideration is needed to accurately measure membrane potentials. However, perseverance to quantify and understand ion selectivity and membrane potentials will be rewarded, as changes in V_m are the primary means by which

cells mediate their function and communicate and coordinate with other cells in our body.

Acknowledgments

Research in the author's laboratory referred to above has been gratefully funded by UNSW Faculty Research Grants, the Australian Research Council, and the National Health and Medical Research Council of Australia. The author thanks Professor Peter Barry for helpful discussions and for the kind permission to use his schematic in Figure 3(b).

Introduction

In 1948, Lehninger and Kennedy showed mitochondria to be the intracellular site of ATP (adenosine triphosphate) synthesis by oxidative phosphorylation (Lehninger and Kennedy, 1948), and in 1953 they were visualized by electron microscopy by Palade (1953). These observations followed from the earlier work in the 1930s of Sir Hans Krebs that animal cells have two important metabolic cycles, i.e., the tricarboxylic acid cycle (TCA cycle), reviewed in Krebs and Johnson (1937), and the urea cycle, reviewed in (Krebs, 1973). Later, the TCA cycle and part of the urea cycle were localized to the mitochondria. Subsequent work revealed that mitochondria have their own DNA (Nass and Nass, 1963), RNA (Wang *et al.*, 2010), and the capacity to synthesize some of their own proteins (Pel and Grivell, 1994). Finally, studies using electron microscopy and other technologies revealed that mitochondria, in terms of numbers, are exceptionally high in nucleated cells. Thus, heart cells may contain about 5000 mitochondria per cell, muscle cells about 2500, and liver cells, 1000–2000. Red blood cells (erythrocytes) that have no nucleus also have no mitochondria. Another view is that a cell has a single mitochondrial reticulum.

By 1967, the use of electron microscopy had broadened, making it possible for several different laboratories to visualize mitochondria clearly and in some detail. Significantly, such studies with either liver mitochondria (Hackenbrock, 1968) or cancer (hepatoma) mitochondria (Pedersen *et al.*, 1970) confirmed that these ATP-producing organelles consist of four major compartments illustrated in Figure 1 and listed as follows:

1. An outer membrane, the subject of this brief article.
2. An inner membrane that consists of invaginations named ‘cristae.’
3. A matrix, a soluble compartment enclosed by the inner membrane.
4. An intermembrane space, the soluble compartment between the inner and outer membranes.

This new information posed many questions, the most obvious being ‘In which of the above four compartments (or major compartments) do known mitochondrial processes take place?’

Separation and Isolation of the Four Mitochondrial Compartments

To address the above question Carl Schnaitman working in the laboratory of Dr. Jack Greenawalt at Johns Hopkins University in Baltimore in the late 1960s took on the challenging project of ‘nailing down’ the submitochondrial locations of known mitochondrial processes and the enzymes/proteins involved.

Several other laboratories at other institutions had also begun similar studies, all with different approaches.

Schnaitman's approach included refrigerated centrifuges with the capacity to sediment cellular homogenates at a relatively low speed, others that would sediment them at a very high speed, and still others that operated somewhere in between the two. To enter the laboratory in which Schnaitman worked in the middle of the night was like entering an aircraft company testing plane engines with the exception that rather than the noise coming from motors inducing propellers to spin, it came from centrifuge motors inducing rotors to spin. Schnaitman also used electron microscopy to visualize the mitochondria before and after treatment with various detergents, mainly digitonin and lubrol WX. In collaboration with V.G. Erwin, he deduced that the enzyme referred to as monoamine oxidase would likely be a good marker for the outer mitochondrial membrane (Schnaitman *et al.*, 1967) and, via titration of a known amount of mitochondria, he found a concentration of the detergent digitonin that ‘teased off’ both (1) the outer membrane and (2) the intermembrane space. The remaining parts of the mitochondria, i.e., the inner membrane and matrix, were left intact together and named ‘mitoplast’ for one and ‘mitoplasts’ for more than one. By treating the mitoplasts with the nonionic detergent Lubrol WX, he was able to separate them into (3) the inner membrane fraction and (4) the soluble ‘matrix’ fraction. Thus, in a single experiment, with appropriate centrifugation steps to separate 1 from 2 and 3 from 4, he could isolate the four components of the mitochondria (Schnaitman and Greenawalt, 1968). Schnaitman also learned how to assay the activity of almost every enzyme known at that time to be associated with the mitochondria. These included enzymes associated with the TCA cycle, urea cycle, and the oxidative phosphorylation system involved in ATP synthesis.

Results: Protein/Enzyme Assignments of the Four Mitochondrial Compartments with an Emphasis on the Outer Mitochondrial Membrane

Subsequent studies by Schnaitman (Schnaitman *et al.*, 1967; Schnaitman and Greenawalt, 1968), in collaboration with the laboratory of Pedersen (Schnaitman and Pedersen, 1968; Pedersen and Schnaitman, 1969; Chan *et al.*, 1970), and work conducted independently in Stockholm (Sottocasa *et al.*, 1967) eventually led to a general consensus that:

1. Enzymes/proteins involved in the ‘electron transport chain’ are located in or associated with the mitochondrial inner membrane.

Figure 1 Schematic diagram of the bottom half of a mitochondrion that allows its various components to be visualized (artwork by Albert Ko, Gerstell Academy, Finksburg, MD, USA).

2. The enzyme complex that makes ATP (ATP synthase) and catalyzes an ATP/ADP exchange reaction inhibited by the ATP synthesis inhibitor 'oligomycin' is associated also with the mitochondrial inner membrane.
3. The key transport systems (adenine nucleotide carrier and phosphate carrier) that transport, respectively, ADP and phosphate into the mitochondria to provide substrates for the catalytic headpiece (F_1) of ATP synthase are localized within the inner membrane. (Once made, the adenine nucleotide carrier also transports the newly synthesized ATP out of the mitochondrial matrix in exchange for another ADP molecule entering the inner compartment.)
4. Most enzymes of the TCA cycle are located within the mitochondrial matrix, but transporters that may move some of the intermediates in or out of the mitochondrial matrix are localized in the inner mitochondrial membrane.
5. Two enzymes involved in the urea cycle are located in the mitochondrial matrix, and three are located in the cytosol.

Based on all the above, early work (late 1960s early 1970s) was targeted much more toward what was happening in the

mitochondrial inner compartments (inner membrane and/or matrix) and less attention was focused on the outer compartments (outer membrane and intermembrane space). However, work conducted in many different laboratories ultimately succeeded in elucidating the protein/enzyme composition of both membranes. Many of these findings and their significance (or possible significance) are summarized in [Table 1](#) as they specifically relate to the outer mitochondrial membrane.

'Moonlighting' Roles of the Mitochondrial Outer Membrane with Its Intracellular Neighbors

An area of mitochondrial research that has not received the attention that has been given to biochemical processes relates to what might be regarded as the 'moonlighting' roles of this organelle, i.e., its interactions with its intracellular neighbors. Such interactions are expected to, and in fact must, involve the outer mitochondrial membrane because it is readily accessible.

Table 1 Enzymes localized in the outer mitochondrial membrane

Enzyme(s)/protein(s)	Tissue/cell type(s)	Significance/possible significance
Acetyl CoA synthase	Liver	Activates breakdown of long-chain fatty acids (Norum <i>et al.</i> , 1966)
Arginosuccinate synthetase	Liver	Converts citrulline into arginosuccinate in the urea cycle (Demarquoy <i>et al.</i> , 1994)
Carnitine palmitoyl transferase	Heart, muscle	Carnitine is an essential cofactor in the beta oxidation of long-chain fatty acids that must be transported into mitochondria (Murthy and Pandey, 1987)
Choline dehydrogenase	Several	Role in betaine aldehyde formation. Also, a role in mitophagy, process by which cells eliminate mitochondria (Park <i>et al.</i> , 2014)
Creatine kinase	Heart, muscle	Bound to VDAC (Bridiczka <i>et al.</i> , 1994); helps provide a temporal and spatial energy buffer to maintain cellular homeostasis (Schlattner <i>et al.</i> , 2001)
Cytochrome <i>b5</i> -like hemoprotein	Rat liver	Cyt <i>b5</i> -like hemoprotein of the outer mitochondrial membrane (Ito, 1980); believed to be involved in NADH-semidehydroascorbic acid reductase activity (Ito <i>et al.</i> , 1981)
Deubiquitinating (Ub-16)	Yeast	May help regulate the turnover or activity of proteins at the outer membrane (Kinner and Kolling, 2003)
Deubiquitinating (USP-30)	Hela and Cos 7 cells	Maintenance of mitochondrial morphology (Nakamura and Hirose, 2008)
DMT1 (divalent metal transporter 1)	Most	Helps mitochondria acquire iron (Wolff <i>et al.</i> , 2014)
Glycolytic (All)	<i>Arabidopsis</i>	Allows pyruvate to be provided directly to mitochondria where it is used as a respiratory substrate (Giege <i>et al.</i> , 2003)
Hexokinase 2 (Hk-2)	Heart	Required for optimal cardiac function. Reduction in Hk-2 levels results in decreased cardiac function and altered remodeling after ischemia/reperfusion injury (Wu <i>et al.</i> , 2012) Also, Hk-2 promotes glycolysis and the production of ATP when oxygen is limiting. Finally, Hk-2 bound to VDAC may prevent cell death as in cancer (Gottlob <i>et al.</i> , 2001; Pastorino <i>et al.</i> , 2002) (see below)
Hexokinase 2 (Hk-2)	Adipocytes	Hk-2 is the main hexokinase in fat pads (Katzen and Schimke, 1965); thus it is likely involved in initiating the conversion of glucose to fat in adipose tissue (Flatt, 1970)
Hexokinase 2 (Hk-2)	Most cancers	Hk-2 bound to mitochondrial VDAC in cancers (Nakashima <i>et al.</i> , 1986) plays a pivotal role (Bustamante and Pedersen, 1977) in the 'Warburg effect,' i.e., high rates of conversion of glucose to lactic acid even in the presence of oxygen. Hk-2 provides glucose-6-phosphate for biosynthesis, and immortalizes cancer cells (Gottlob <i>et al.</i> , 2001; Pastorino <i>et al.</i> , 2002). Also, Hk-2 bound to VDAC is the enzymatic basis of PET imaging used worldwide to detect and monitor cancers
Kynurenine hydroxylase	Widespread	Involved in degradation pathway for tryptophan (Guillemin <i>et al.</i> , 2007). Associated with disorders of the brain (Shilov and Bezrukov, 2013)
Mitochondrial Ubiquitin ligase (MITOL)	Widespread	Involved in mitochondrial dynamics Eliminates misfolded proteins that localize to mitochondria, for example, superoxide dismutase (mSOD1) (Yonshiro, 2006). Mitol also regulates ER contacts via mitofusin 2 (Sugiura <i>et al.</i> , 2013)
Monoamine oxidase	Widespread	Maintains neuron firing rates throughout the body by metabolizing in the liver bioactive amines absorbed into the blood from food (Richardson, 1993)
NADH cyt <i>b5</i> reductase	Rat liver	Not clear but similar or identical with the microsomal NADH-cyt <i>b5</i> reductase (Sottocasa <i>et al.</i> , 1967)
OM 14	Yeast	OM 14 is a receptor for NAC, ribosome-associated chaperone nascent-chain associated complex (Lesnik <i>et al.</i> , 2014)
NADH cyt <i>c</i> reductase TOM	Rat liver Most cells	May participate in NADH semi-hydroascorbic acid reductase activity (Ito <i>et al.</i> , 1981) Translocase of the outer membrane that moves proteins into the intermembrane space (Neupert and Herrmann, 2007). There are a number of different TOMs, for example, TOM 5, TOM 6, TOM 7, TOM 20, TOM 22, TOM 40, and TOM 70. The TOM proteins work with TIM proteins (translocases of the inner membrane), for example, TIM 17, TIM 18, TIM 22, TIM 23, TIM 44, TIM 50, TIM and TIM 54, to move proteins into the mitochondrial matrix
VDAC	Most cells	A voltage-dependent anion channel in the outer mitochondrial membrane that is implicated as a governor of mitochondrial function (Colombini, 2004); its roles in health and disease are numerous. VDAC is essential for mitochondrial function in almost all cell types in humans and animals. However, when cells become cancerous in animals and humans VDAC, perhaps wanting to keep its job, participates in their immortalization by hijacking Hk2 (Pastorino <i>et al.</i> , 2002)

Mitochondrial Endoplasmic Reticulum Interactions

Several studies have shown that parts of the endoplasmic reticulum (ER) are intimately associated with the mitochondrial

outer membrane with one of the earliest reports occurring in Copeland and Dalton (1959). Shore and Tata (1977) reported rapidly sedimenting ER in association with mitochondria. In a follow-up study, Pickett *et al.* (1980), via sedimentation and

microscopic analysis, provided evidence for rough ER mitochondrial complexes. Filippin *et al.* (2003) concluded that stable interactions do occur between mitochondria and the ER and that this allows for a rapid accumulation of calcium in a subpopulation of mitochondria. Malhotra and Kaufman (2011) commented on what they referred to as 'ER stress,' its functional link to mitochondria and role in cell survival and death. Finally, Flis and Daum (2013) in a detailed report emphasize the importance of lipid transport between the ER and mitochondria that would necessitate involvement of the outer mitochondrial membrane.

Mitochondrial–Nuclear Interactions

Although a limited amount of work has been conducted on mitochondrial–nuclear interactions this is likely to prove to be quite significant as more work is completed. Five studies are briefly summarized here. First, in a report published, Ornstein (1956) described 'a remarkable relationship which occurs during a limited phase of this early development between the nuclear processes and the mitochondria of the oocyte.' The author goes on to state, "Here we see that the mitochondria are closely applied to the denser material which seems to be continuous with the nuclear membrane processes-as if we have caught the nucleus and the mitochondria in the process of cooperatively producing the denser masses". Mota (1963) described mitochondria that he had observed in the plant *Chlorophytum capense* (L.) Kuntz. He stated, "Electron microscope studies of tips of aerial roots of *Chlorophytum capense* (L.) Kuntz showed the formation in the nucleus of a large number of invaginations in which mitochondria accumulate. These mitochondria are seen in many cases attached to the nuclear membrane, which appears destroyed at the point of attachment, as if the mitochondria were exchanging some substances with the nucleus or were being absorbed by the nucleus. This phenomenon can conceivably be a mechanism to transfer ATP and possibly other substances from the mitochondria to the nucleus. Intimate contact between mitochondria and the nuclear membrane may be only a 'touch and go' and only involve a small portion of the mitochondrial surface". (This would of course be the outer membrane.)

Jensen *et al.* (1976) described myocardial cells derived from a 60-year-old patient with rheumatic heart disease undergoing cardiopulmonary bypass surgery. Surprisingly, such cells were found to contain mitochondria with well-preserved membranes within their nuclei. For such mitochondria to have entered the nuclei, the mitochondrial outer membrane would have had to interact first with the nuclear membrane. Two other later studies provided further evidence for mitochondrial–nuclear interactions and/or communication. Dzeja *et al.* (2002) monitored the import of histone H1, a constitutive nuclear protein into the nucleus and found mitochondria to cluster around the nucleus reducing the distance for energy transfer and in so doing undergoing interactions of their outer membrane with the nuclear membrane. One year later Prachar (2003), in briefly summarizing the study, states, "Mitochondria in close proximity to the nuclear envelop can be found virtually in all metabolically active cells. We used transmission electron microscopy to demonstrate this entity in

different leukemia cells of human origin (patient's blood) and in a mouse leukemia cell line. At high resolution, not only close proximity but even fusion of mitochondrial and nuclear membranes can be seen. Based on available data about mRNA transport through the nuclear pore complex and observed contacts of mitochondria with nuclei, we hypothesize that such contacts can provide a gateway for energy delivery to power mRNA export from the nucleus to the cytoplasm."

Mitochondrial Interactions with the Golgi, Peroxisomes, and Plasma Membrane

From the observations noted, it is clear that mitochondria have developed quite a social network within cells. This network is considered to be highly dependent on the outer mitochondrial membrane as it is the only compartment of a mitochondrion that is in a position to enter into direct contact with intracellular neighbors. In addition to having been reported to interact with the ER and nucleus of cells, mitochondria have been reported to interact also with the Golgi, peroxisomes, and the plasma/cell membrane. Dolman *et al.* (2005) reported stable Golgi–mitochondrial complexes and the formation of Golgi Ca^{2+} gradients in pancreatic acinar cells. They state, "The Golgi is ideally placed to be preferentially supplied by ATP from adjacent mitochondria." As it relates to interaction of mitochondria with peroxisomes, both Neuspiel *et al.* (2008) and Borgue and Demarquoy (2012) have reported such interactions, the latter article related to a possible role in fatty acid metabolism, and referred to as the 'mitochondria–peroxisome connection,' by Smallridge (2008). Finally, and likely equally or more significant is the finding of mitochondrial plasma membrane contacts (Klecker *et al.*, 2013). The work involving yeast characterized mitochondrial–plasma membrane interactions identifying Num1 (nuclear migration one) as a protein involved in the process. Num 1 is a 313 kDa protein that binds to the plasma membrane by a plekstrin homology (PH) domain and assembles into cortical patches. Num 1 is sometimes referred to as a cell cortex protein, where the cell cortex is defined as a specialized layer of cytoplasm on the inner face of the plasma membrane that functions as a mechanical support for it.

Involvement of the Outer Mitochondrial Membrane in Major Diseases and Potential Drug Target

Cancer

Cancer, according to the World Health Organizations Fact Sheet N 297 updated in 2014 (Stewart and Wild, 2015), figures among the leading causes of morbidity and mortality worldwide with approximately 14 million new cases and 8.2 million cancer-related deaths in 2012. Moreover, the number of new cases is expected to rise about 70% over the next 2 decades. It is known that the outer mitochondrial membrane is one of cancers' best friends. This was first recognized by Bustamante and Pedersen (1977). Specifically, they demonstrated that a form of hexokinase bound to a protein in mitochondria, later shown to be the outer membrane VDAC protein (Nakashima *et al.*, 1986), is intimately involved in the 'Warburg effect,' i.e., high glycolysis even in the presence of

oxygen. Significantly, this produces large amounts of the glucose-6-phosphate utilized in biosynthetic reactions essential for the rapid growth and division of cancer cells. However, as shown later by others, Hk-2 bound to VDAC is involved also in the immortalization of cancer cells (Gottlob *et al.*, 2001; Pastorino *et al.*, 2002) and a detection system (positron emission tomography, PET) was developed a number of years ago based on hexokinase (Som *et al.*, 1980) and is now used worldwide to detect cancers and monitor their treatment.

In more recent research, it was shown that one of the targets of the rapidly effective anticancer agent 3-bromopyruvate (3BP) is outer mitochondrial membrane bound Hk-2 (Ko *et al.*, 2001). In studies with 19 animals bearing advanced cancers carried out by Ko *et al.* (2004), 3BP was found to eradicate them all, i.e., 100%. Moreover, the cancers never returned throughout the lifetime of the animals. 3BP, when properly formulated, was found to be applicable also to human cancer. Thus, the life of one teenage boy suffering from liver cancer was significantly extended (Ko *et al.*, 2012).

In summary, the outer mitochondrial membrane is intimately involved in the rapid growth and immortality of cancer via bound Hk-2, and this enzyme has provided via PET imaging the basis for cancer detection and monitoring as well as a target for the potent anticancer agent 3BP.

Heart Disease

According to a report by Murphy *et al.* (2013), about 600 000 people die of heart disease in the United States every year. It accounts for one in four deaths. As for cancer cells, heart cells (cardiomyocytes) have Hk-2 bound to their outer mitochondrial membrane, and at this location it is believed to be essential not only for (1) every beat, but also for (2) the lifetime of the heart and, therefore, (3) human/animal lifetime. As Smeele *et al.* (2011) emphasized from results of their studies, "Disruption of Hexokinase II (Hk-2) mitochondrial binding blocks ischemic preconditioning and causes rapid cardiac necrosis." They go on to state that "The present data demonstrate that HK II (Hk-2) detachment from mitochondria results in acute mitochondrial depolarization, which is likely the mechanism of cardiac dysfunction." Also, Wu *et al.* (2012) reported that a reduction in Hk-2 levels results in decreased cardiac function and altered remodeling after ischemia/reperfusion injury. Finally, Anflous *et al.* (2007) have shown recently that VDAC1 serves as a mitochondrial binding site for hexokinase in oxidative muscles. The authors refer to "Hk-2 detachment from mitochondria," which most likely means detachment from its binding to VDAC1 in the outer mitochondrial membrane.

Alzheimer's Disease (AD)

First, in the United States, it was reported (Alzheimer's Association, 2014) that:

1. An estimated 5.2 million Americans of all ages have AD (year 2014).
2. One in nine aged 65 and older (11%) has AD.
3. About 1/3 of people 85 and older (32%) have AD.

4. Of those with AD, the vast majority (82%) are aged 75 or older.

In a second report that appeared also this past year (Prince *et al.*, 2014), worldwide:

1. Dementia, including AD, remains one of the biggest global health challenges facing our generation.
2. The number of people living with dementia worldwide today is estimated at 44 million, set to double by 2030 and more than triple by 2050.
3. The global cost was estimated in 2010 to be US\$604 billion. Therefore, by the year 2050 the total cost will exceed US\$1812 billion.

So what is the relationship of the mitochondrial outer membrane to AD and dementia? It has been known for some time that a component of the brains of deceased Alzheimer's patients contain plaques referred to as 'amyloid plaques' that are comprised of peptides 36–43 amino acids in length. Some of these are imported into mitochondria via the outer membrane TOM import machinery and localize to mitochondrial cristae (Hansson Petersen *et al.*, 2008). In particular, a channel forming subunit of TOM referred to as TOMM40 that is essential for protein transport into mitochondria has received recent attention. In humans certain alleles of the gene encoding TOMM40 have been statistically associated with an increased risk of late on-set AD. Thus, in a genome-wide association study on 381 participants in the ADNI (Alzheimer's Disease Neuroimaging Initiative) study, TOMM40 risk alleles were approximately twice as frequent in AD subjects as controls (Potkin *et al.*, 2009).

Concluding Remarks

The mitochondrial outer membrane plays highly important roles in both health and disease. It is not simply a protective cover for the mitochondrial inner membrane plus matrix compartments where the TCA cycle and oxidative phosphorylation take place, but rather is very active, in fact much more active than most investigators realize. As described, the outer membrane on a day-to-day basis interacts with the ER, the nucleus, Golgi, peroxisomes, and plasma membranes. Interestingly, when cells become diseased, the mitochondria, perhaps to survive, appear to take on properties to facilitate the disease. It seems that whether we are healthy or contract a disease, a better understanding of the role of mitochondria in these processes will be important for many aspects of human and animal health.

Acknowledgments

PLP was supported for many years by the National Cancer Institute, for which he is grateful.

Neuronal Action Potentials and Ion Channel Allostery

SE Kotermanski and M Cascio, Duquesne University, Pittsburgh, PA, USA

© 2016 Elsevier Inc. All rights reserved.

Glossary

Action potential A highly coordinated sequence of events that requires the activation of voltage-gated Na^+ and K^+ channels which generates an all-or-nothing wave of electrical activity. Initiated at the axon hillock an action potential travels along the length of the axon until reaching the axon terminal where it results in the activation of voltage-gated Ca^{2+} channels and release of neurotransmitter.

Electrochemical gradient A result of ionic concentration differences between two areas (such as the intracellular and extracellular space) and the electrical potential associated with relevant ions. These two properties determine which direction a permeant ion will move between the two areas. Electrochemical gradients provide a source of energy in which cells can use to transmit information as well as various other processes (such as an energy source for transport proteins).

Excitatory postsynaptic potentials (EPSP) A transient depolarization of the neuronal cell membrane that results from the opening of ligand-gated ion channels that are typically permeable to Na^+ , K^+ , and/or Ca^{2+} . EPSPs increase the probability of an action potential being generated by driving the neuronal membrane potential toward the threshold potential.

Inhibitory postsynaptic potentials (IPSP) A transient hyperpolarization of the neuronal cell membrane that results from the opening of ligand-gated ion channels that are typically permeable to Cl^- . IPSPs decrease the probability of an action potential being generated by driving the neuronal membrane potential away from the threshold potential.

Ionotropic receptors Receptors that consist of a pore region that opens in response to a variety of stimuli (such as ligand binding, voltage, or mechanical stimuli). Once activated, permeant ions (typically Na^+ , K^+ , Ca^{2+} , or Cl^-) rapidly pass through the pore of the channel in a direction determined by their electrochemical gradient.

Membrane potential The electrical potential difference (usually stated in mV) between the intracellular and extracellular surface of the cell membrane at any given

moment. The membrane potential varies over time as a result of the activity of ionotropic receptors.

Metabotropic receptors Unlike ionotropic receptors, metabotropic receptors do not contain a permeant ion pore which allows for the passage of ions upon activation. Metabotropic receptors contain an extracellular ligand-binding domain and an intracellular G-protein binding domain. The binding of ligand to metabotropic receptors results in activation of G-proteins that dissociate from the receptor and transduce the signal by activating intracellular pathways, resulting in a less rapid signaling cascade.

Resting membrane potential The electrical potential of a cell in the absence of synaptic activity. Results from the unequal distribution of charged particles between the intracellular and extracellular space. The unequal distribution of charges is the result of the activity of electrogenic pumps. The extracellular space is conventionally defined as neutral and the inside of the cell typically lies between -60 and -70 mV.

Saltatory conduction Used to describe action potential conduction along myelinated axons. In myelinated axons action potentials jump between nodes of Ranvier which contain a high concentration of voltage-gated Na^+ channels that serve to regenerate the signal strength which then passively propagates along the internode regions. This mechanism dramatically increases the rate of action potential propagation.

Synapse The region between the axon terminal of a neuron and its target. Synapses are areas where the cell membrane of a neuron and its target come into close proximity of each other. Information is then passed from the presynaptic cell to the postsynaptic cell either by an electrical connection via gap junctions or through the release from the presynaptic cell of chemical neurotransmitters that bind to receptors on the postsynaptic cell.

Threshold potential The critical membrane potential needed to be reached in order to open voltage-gated Na^+ channels and initiate an action potential. The threshold potential typically lies between -40 and -55 mV.

Introduction

An organism's ability to sense, process, and respond to cues in their environment as well as regulate essential physiological processes (such as heart rate and respiration) necessary for life is dependent upon rapid and reliable communication between neurons of the nervous system as well as between neurons and their target tissues. Neurons use a combination of electrical and chemical signals to accomplish this task. Electrical transmission of signals within (and across) neurons as well as

the conversion of chemical signals at the synapse into an electrical signal is possible due the presence of highly selective channels that allow for the passage of ions across the cell membrane. The activity of these ion channels is regulated by either changes in the neurons membrane potential (voltage-gated), the binding of chemical transmitter (ligand-gated), or mechanical stimuli (stretch receptors). The direction of ion flux through activated channels is dependent upon their electrochemical gradient and can shift the neuronal membrane potential more negative (hyperpolarization) or more positive

(depolarization) in relation to the neurons resting membrane potential. A large enough depolarizing stimulus (~ 10 mV from rest) can result in the firing of an action potential, which leads to transmitter release into the synapse and subsequent passage of information to the postsynaptic neuron (Kandel *et al.*, 2000; Hille, 2001; Purves *et al.*, 2012). (These sources were invaluable and were a source for much of the general information throughout this article.)

Electrical Properties of Neurons

The structure of the neuronal cell membrane creates an effective barrier between the intracellular and extracellular environments. The organization of the lipid bilayer (~ 6 – 8 nm thick) consists of two leaflets of non-covalently associated amphiphilic lipid molecules with their exterior facing water accessible polar head groups separated by a thin layer of interior hydrophobic lipid tails (Pfenninger, 1978). The close-packing of the hydrophobic interior of the leaflets, comprised of apposed lipid tails, excludes water and provides a very high energy barrier for the passage of charged particles across the cell membrane, while the polar head groups allow for the accumulation of charged particles along the surface of the cell membrane. This separation of charged particles allows for a potential difference between the inside and outside of the neuron. The only effective way for charged particles to traverse the cell membrane is through specialized proteins incorporated into the lipid bilayer. These proteins may be transporters or ion channels, and amongst the many stimuli that they are responsive to, may be gated by ligands, mechanical stress, temperature, or voltage.

The resting membrane potential is the voltage difference that exists across the neuronal membrane and is typically between -60 mV and -70 mV. By convention the outside of the cell is generally considered to be neutral, resulting in the inside of the cell resting at a negative potential. The value of the resting membrane potential is determined by the concentration of ions in the intracellular and extracellular space as well as the presence of non-gated (leak) channels and electrogenic pumps that move ions across the cell membrane at the expense of energy. The concentration difference of two highly important ions (sodium (Na^+) and potassium (K^+)) involved in neuronal signaling is also maintained by the activity of the Na^+/K^+ pump (Na^+/K^+ ATPase) (Yu, 2003; Wright, 2004). A large percentage of cellular energy is utilized by Na^+/K^+ ATPase, an integral membrane protein (Shinoda *et al.*, 2009) that pumps out 3 Na^+ for every 2 K^+ in, at the cost of a single ATP (with this stoichiometry contributing to the relatively electronegative interior of resting cells).

The direction of ion flow through leak channels is determined by the concentration difference on either side of the cell membrane (as maintained by pumps such as Na^+/K^+ ATPase) as well as the electrical charge associated with that ion. Simple diffusion states that a particle will move from an area of high concentration to an area of low concentration, however, since ions are charged their direction of movement is also influenced by the voltage difference between the intracellular and extracellular space. Since the resting membrane potential is negative, cations would be pulled inside the

cell with the reverse being true for anions, based on electro-motive force alone. The direction of the passive flow of ions through open channels is determined by the electrochemical gradient, the sum of the chemical and electrical gradients, and the equilibrium potential, E_{ion} , where these two forces are equivalent, resulting in no net flux of the ion through an open channel, was defined by Nernst, such that:

$$E_{\text{ion}} = \frac{RT}{zF} \ln \frac{[\text{ion}]_{\text{ext}}}{[\text{ion}]_{\text{int}}}$$

where R is the gas constant, T is the temperature in degrees Kelvin, z is the valence of the ion, F is the Faraday constant, and $[\text{ion}]_{\text{ext}}$ and $[\text{ion}]_{\text{int}}$ is the extracellular and intracellular ionic concentration, respectively (Wright, 2004).

Typically the electrochemical gradient for the major ions involved in neuronal signaling would result in Na^+ , calcium (Ca^{2+}) and chloride (Cl^-) influx and K^+ efflux when channels permeant for each respective ion are activated. An influx of Na^+ or Ca^{2+} would result in a depolarizing stimulus making the membrane potential more positive and K^+ efflux would hyperpolarize the membrane potential making it more negative. Since Cl^- is associated with a negative charge its influx would also serve to hyperpolarize the membrane potential. Of note, under typical conditions the equilibrium potential for Cl^- , E_{Cl} , is very close to the resting potential of a neuron. Thus, small changes in the low $[\text{Cl}^-]_{\text{int}}$ can dramatically affect the direction of flow through Cl^- selective channels. During early development the $[\text{Cl}^-]_{\text{int}}$ of immature neurons is higher than in mature neurons of the adult resulting in an efflux of Cl^- through activated channels, thereby leading to a depolarizing stimulus. During development, there is increased expression of a K^+/Cl^- cotransporter (KCC2), which shuttles one K^+ and one Cl^- ion out of the cell thereby reducing the $[\text{Cl}^-]_{\text{int}}$, resulting in a change in activated Cl^- channels from being depolarizing (inward flux) to hyperpolarizing (outward flux) (Laube *et al.*, 2002; Kirsch, 2006; Avila *et al.*, 2013).

Anatomy of a Neuron and Flow of Information

The neuron doctrine states that the basic signaling unit of the nervous system are separate discrete cells with processes arising out of the cell body. Neurons can be divided into many different classifications based on the number of processes arising from the cell body. Typical neurons share four regions: the cell body (soma), dendrites, axon, and axon terminal. Each region is distinctly organized for its role in the transmission of information. The cell body contains the nucleus and is responsible for gene expression and cellular metabolism. The dendrites and axon arise from the cell body. Dendrites typically have many branches and can form elaborate dendritic trees that receive incoming information to the neuron. The expansive dendritic tree of Purkinje cells of the cerebellum can receive information from approximately 150 000 synapses. Chemical transmission at the synapses of the dendrites gets converted into an electrical signal that gets passively conducted toward the cell body. The cell body integrates this information along with incoming signals arising from synapses onto the

cell body itself. Also arising from the cell body is a specialized region called the axon hillock which gives rise to the axon. The axon hillock is a region of the neuron with a high density of voltage-gated Na^+ channels (for review of voltage-sensing, see Catterall, 2010). If the summation of signals in this region of the neuron depolarizes the cell beyond a threshold potential, an action potential is initiated which is actively propagated along the axon to the axon terminal (Kress and Mennerick, 2009). The action potential activates voltage-gated Ca^{2+} channels in the axon terminal. The resulting transient increase in $[\text{Ca}^{2+}]_{\text{int}}$ results in fusion of neurotransmitter-containing vesicles, and the release of the neurotransmitter from these synaptic vesicles into the synaptic cleft (Sudhof, 2004, 2013) leading to chemical activation of corresponding ligand-gated ion channels on the postsynaptic neuron and subsequent passage of information.

For a neuron to fire an action potential a depolarizing stimulus must be strong enough to reach threshold at the axon hillock. The activation of excitatory ion channels due to release of glutamate (Glu), acetylcholine (ACh), or serotonin (5-hydroxytryptamine (5-HT)) at a single synapse on the dendrite of a neuron results in a subsequent depolarizing electrical signal, however that lone signal will not be large enough to generate an action potential. The signal may also be inhibitory, as the Cl^- channels activated by γ -aminobutyrate (GABA) or glycine (Gly) typically lead to hyperpolarization in adult neurons (as described earlier, increased $[\text{Cl}^-]_{\text{int}}$ can result in depolarization upon activation of these channels) (Laube *et al.*, 2002; Kirsch, 2006; Avila *et al.*, 2013). Neurons receive thousands of incoming depolarizing (excitatory postsynaptic potentials (EPSP)) and hyperpolarizing (inhibitory postsynaptic potentials (IPSP)) stimuli. IPSP and EPSP stimuli are integrated together as the signal travels toward the axon hillock, and it is the summation of these incoming signals that determines whether or not an action potential will be generated (Zheng and Raman, 2010).

Depolarizing and hyperpolarizing stimuli are influenced by the neuron's axial (r_a) and membrane resistances (r_m). The magnitude of incoming stimuli to a neuron decreases as it travels away from its point of origin. This occurs due to the effects of r_a , the resistance of the cytoplasm that the signal encounters as it travels along the length of the dendrite. The membrane resistance of a pure lipid bilayer is very high, however, the presence of leak channels within the membrane allows for current to pass out of the neuron instead of coursing through it, also decreasing the magnitude of the stimuli as a function of the distance the signal propagates. The nervous system has developed a way of increasing the resistance of regions of its cell membrane by adding insulating layers of membrane, called myelination (Pfenninger, 1978). Myelination decreases the loss of current through the cell membrane, thereby allowing for a stimulus to travel further with limited degradation. The length constant (λ) of a neuron is the distance in which a signal decays to $1/e$, or approximately 37%, of its original magnitude and can be calculated by the following equation:

$$\lambda = \sqrt{\frac{r_m}{r_a}}$$

A measure of how fast a stimulus decays at the point of initiation is the time constant (τ). The longer the time constant the longer the stimulus will remain at the point of initiation

leading to a greater chance of summation with subsequent signals to occur.

Taken together, these parameters describe how far from the point of initiation and how long after initiation a given stimulus will alter the membrane potential from rest. Spatial summation results when the effects of two stimuli arising from different areas of the neuron interact, and temporal summation occurs when a second stimulus arrives at a synapse before a previous stimulus has had time to fully decay. The final effect of integrating the multitude of incoming signals to a given neuron determines whether that neuron will fire an action potential (the threshold potential, described in the next section), resulting in the postsynaptic release of chemical neurotransmitter and the propagation of information to other neurons to which it is synaptically connected. If the summation of all synaptic stimuli arriving along the dendrites and cell body of a neuron result in a depolarization strong enough to reach threshold at the axon hillock an action potential will be initiated.

Action Potentials

The action potential is an all-or-nothing electrical wave that is initiated at the axon hillock and propagates toward the axon terminal via highly coordinated sequential activation of various ion channels that have differential selectivities with respect to ion permeation (Figure 1). Action potentials are not graded signals like EPSPs or IPSPs, and are either initiated fully or not at all. Although the shape of an action potential is relatively consistent across the many types of neurons within the nervous system, variations in ion channel properties do introduce some differences (Kress and Mennerick, 2009).

The axon hillock contains a very high concentration of voltage-gated Na^+ channels that become activated once a critical membrane potential is reached, the threshold potential. The threshold potential is a membrane depolarization of approximately 10 mV from rest. This change in voltage results in a conformational change of the voltage-gated Na^+ channel that opens up a central pore that is highly selective for Na^+ , allowing its influx as directed by its electrochemical gradient (Bezaniila, 2006). This influx further depolarizes nearby areas of the cell. Voltage-gated Na^+ channels are a single polypeptide chain of amino acids that contain four repeating homologous domains each containing six transmembrane segments (S1–S6) and a re-entrant pore-lining region (P region) that lies between the S5 and S6 segments (Payandeh *et al.*, 2011). The four P regions of the protein contain chemical groups that effectively replace the hydration shell of Na^+ and stabilize the charge on the dehydrated Na^+ as it passes through the selectivity filter of the pore (which is specific for Na^+ , and impermeant to K^+). The S4 region, although mostly hydrophobic, contains positively charged amino acids that sense the voltage difference across the cell membrane. It is hypothesized that this portion of the protein moves in response to membrane depolarization, thereby causing a conformation change in the channel allowing for the opening of an activation gate and flux of Na^+ through the channel. Voltage-gated Na^+ channels inactivate in a manner that is distinct from just the simple closing of the

Figure 1 Representative trace of an action potential. EPSPs resulting from the activation of ligand-gated ion channels (such as members of the ligand-gated family of glutamate receptors) depolarizes the neuronal membrane potential, V_m , from its resting potential (~ -70 mV) (A) toward the threshold potential (~ -55 mV). Once the threshold potential is reached voltage-gated Na^+ channels begin to open allowing for Na^+ influx and further depolarization of the neuronal membrane and (B) the rise of the membrane potential toward E_{Na} ($\sim +55$ mV) resulting in the upswing (or rising phase) of the action potential. The membrane depolarization also opens voltage-gated K^+ channels, whose opening kinetics are slower than that of voltage-gated Na^+ channels, (C) resulting in the peak of the action potential and preventing it from rising all the way to E_{Na} . The efflux of K^+ as well as the slow inactivation of voltage-gated Na^+ channels results in (D) the downswing (or falling phase) of the action potential. V_m falls toward E_{K} (~ -80 mV) (the after hyperpolarization) and (E) gradually returns toward the resting membrane potential (F) as voltage-gated K^+ channels close and resting ionic gradients are returned by the actions of leak channels and the Na^+/K^+ ATPase.

activation gate. The inactivation gate of voltage-gated Na^+ channels also closes as a result of depolarization, however, more slowly than the opening of the activation gate. This results in a brief window (milliseconds) during which both gates are open and (Na^+) can pass and allow for the neuronal membrane potential to approach E_{Na} (typically $\sim +55$ mV). This sequence of events results in the upswing or rising phase of the action potential. It is not until the membrane potential returns to near rest that both gates reset and voltage-gated Na^+ channels resume their resting conformation of a closed activation gate and open inactivation gate. Until voltage-gated Na^+ channels return to their resting conformation, another action potential cannot be initiated since the channels are inactivated and unable to allow Na^+ influx. The time it takes for voltage-gated Na^+ channels to return to their resting confirmations and therefore allow for the initiation of another action potential is called the absolute refractory period.

The downswing, or falling phase, of action potentials results from the subsequent opening of voltage-gated K^+ channels, as well as voltage-gated Na^+ channel inactivation. Voltage-gated K^+ channels also contain six transmembrane regions (S1–S6) and a re-entrant P region between S5 and S6 (Jiang *et al.*, 2003). However, each gene product of voltage-

gated K^+ channels contains only one copy of this sequence. Four subunits assemble to produce the functional channel that is highly selective for K^+ . Similar to voltage-gated Na^+ channels, it has been shown that the P region lines the central pore and the S4 region is involved in channel activation of voltage-gated K^+ channels. Voltage-gated K^+ channels are activated by membrane depolarization as well, however their activation occurs more slowly than voltage-gated Na^+ channels. When activated, K^+ flows out of the cell along its electrochemical gradient, thereby bringing the membrane potential back near E_{K} (typically ~ -80 mV), which is more negative than the resting membrane potential (after hyperpolarization). The return of the membrane potential toward rest results in the closing of voltage-gated K^+ channels (unlike voltage-gated Na^+ channels, they do not contain an inactivation gate). The slow closing of voltage-gated K^+ channels also makes it more difficult to initiate another action potential since the latent permeability to K^+ will keep the neuronal membrane further from the threshold potential necessary to activate voltage-gated Na^+ channels. This relative refractory period lasts until voltage-gated K^+ channels return to their closed resting confirmations. During the relative refractory period, it is possible to generate another action potential, however, a stronger stimulus is required.

Action Potential Propagation

Action potentials are rapid changes in the membrane potential of neurons that transmit information throughout the nervous system. Once initiated at the axon hillock, the action potential will propagate down the length of the axon (which may be as long as a meter in length in humans) until it reaches the axon terminal. Membrane depolarization occurring at one area of the axon passively spreads to and depolarizes adjacent areas. This activates voltage-gated Na^+ channels in the adjacent areas resulting in Na^+ influx and propagation of the signal. Although the influx of Na^+ would diffuse in both directions along the length of the axon, the refractory periods prevent back propagation of the signal. While still rapid, action potential propagation rate is limited by the relatively small diameter of the axon which creates high r_a . Increasing the diameter of the axon would increase the rate of signal propagation, however, this is not evolutionarily feasible due to the large number of axons that exist in the vertebrate nervous system. Myelination of axons by glial cells increases the rate of action potential propagation while still allowing for the small diameter of axons. In general the conduction velocity of an action potential in unmyelinated axons ranges from 0.5 to 10 m s^{-1} and up to approximately 150 m s^{-1} in myelinated axons.

Oligodendrocytes and Schwann cells are specialized glial cells of the nervous system that wrap the axons of neurons with multiple layers of their own cell membrane. This increases r_m preventing the loss of current across the axonal membrane resulting in the signal propagating further along its length. However, the multiple overlapping layers of membrane prevents the incorporation of voltage-gated Na^+ channels that are needed to regenerate the action potential, therefore the signal strength decreases along the length of the axon. This degradation in signal strength is compensated by

leaving spaces ($\sim 2 \mu\text{m}$ in length) of the axon without myelination, called the nodes of Ranvier that contain a high concentration of voltage-gated Na^+ channels. The action potential signal passively propagates along the myelinated internode areas ($\sim 1\text{--}2 \text{ mm}$ in length) until reaching these nodes and activating their Na^+ channels, regenerating the strength of the action potential. This method of saltatory conduction where the action potential signal jumps from node to node drastically increases the speed of action potential propagation.

Action Potential Invasion of the Nerve Terminal

Action potential propagation terminates at the axon terminal, which contains synaptic vesicles that contain neurotransmitter, as well as the machinery needed to release that neurotransmitter into the synaptic cleft (described below). Of critical importance to the release of neurotransmitter upon action potential invasion are voltage-gated Ca^{2+} channels located in the axonal terminus. The structure of voltage-gated Ca^{2+} channels are thought to be homologous to that of voltage-gated Na^+ channels, consisting of a single polypeptide chain that contains four repeating segments of six transmembrane domains (S1–S6) and a re-entrant pore-lining region (P region) between S5 and S6 (Simms and Zamponi, 2014). Like voltage-gated Na^+ channels, voltage-gated Ca^{2+} channels activate in response to membrane depolarization, although much more slowly, allowing for Ca^{2+} influx along its electrochemical gradient. Voltage-gated Ca^{2+} channels begin to allow Ca^{2+} influx near the end of the action potential and the duration of their open time depends on the time course of the action potential. Voltage-gated Ca^{2+} channels inactivate in response to the repolarization of the membrane potential back to resting levels as well as a Ca^{2+} dependent feedback inactivation via cytosolic regulation. $[\text{Ca}^{2+}]_{\text{int}}$ is highly regulated and maintained in the cytoplasm at very low levels, as higher concentrations are toxic. Ca^{2+} is a common second messenger in cells, as this divalent cation is an allosteric regulator of a wide range of Ca^{2+} binding proteins (Villereal and Palfrey, 1989).

Only a small percentage ($\sim 1\%$) of synaptic vesicles present at the axon terminal are immediately available to participate in neurotransmitter release. These vesicles are docked near the neuronal plasma membrane and constitute the readily releasable pool of vesicles. The other pools of vesicles are the reserve pool and the recycling pool (Rizzoli and Betz, 2005). Synaptic vesicles contain transport proteins that are responsible for filling the vesicle with neurotransmitter and soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins which facilitate vesicular docking and fusion. According to the SNARE hypothesis, the vesicular SNARE protein synaptobrevin forms a complex of four α helices with the neuronal membrane SNARE proteins syntaxin and SNAP-25, which primes the vesicle for fusion with the neuronal membrane (Rizo and Rosenmund, 2008). Other cytosolic proteins have also been proposed to assist in the SNARE complex formation (Weimer and Richmond, 2005; Shin *et al.*, 2010; Trimbuch *et al.*, 2014). The synaptic vesicle associated protein, synaptotagmin, contains multiple Ca^{2+} coordination sites and acts as a Ca^{2+} sensor for triggering vesicle fusion

with the neuronal membrane. The exact mechanism of synaptic vesicle fusion and release of neurotransmitter is still unknown. Evidence exists for a full fusion model where the synaptic vesicle fully fuses and collapses into the neuronal membrane releasing its transmitter into the synaptic cleft. However, evidence also exists for a kiss-and-run model of transmitter release where only a small fusion pore connecting the vesicular and neuronal membranes opens briefly allowing for neurotransmitter to diffuse into the synaptic cleft (Rizzoli and Betz, 2005; Rizo and Rosenmund, 2008).

Fate of Neurotransmitter in the Synaptic Cleft

Once released into the synaptic cleft, neurotransmitter can bind to receptors located on the postsynaptic membrane resulting in the transfer of information from one neuron to the next. The extent of the postsynaptic response to transmitter release is dependent on neurotransmitter local concentration, the total number of receptors present on the postsynaptic membrane, and their functional characteristics (e.g., ligand affinity and kinetics). The postsynaptic response is dependent on the duration of time that the transmitter is present in the synaptic cleft. Removal of neurotransmitter from the synaptic cleft occurs through simple diffusion out of the cleft, enzymatic degradation of neurotransmitter, binding of neurotransmitters by binding proteins, or reuptake of neurotransmitter back into the presynaptic nerve terminal by protein transporters.

Many neurological agents act by affecting the nervous systems mechanism of removing neurotransmitter from the synaptic cleft. For example, nerve gases such as sarin inhibit the activity of acetylcholinesterase (AChE), the enzyme that acts to degrade Ach into acetate and choline, thereby terminating its signal (Abu-Qare and Abou-Donia, 2002). The mechanism of action of cocaine is to inhibit the reuptake activity of the dopamine, norepinephrine and 5-HT transporters that function to transport their respective ligands back into the presynaptic neuron. An area of the brain that plays an important part in processing rewarding and pleasurable stimuli, the nucleus accumbens, receives signals from dopaminergic neurons of the ventral tegmental area. The rewarding effects of cocaine is believed to lie in its ability to increase activity of neurons in the nucleus accumbens by inhibiting the reuptake of dopamine (DA) into the presynaptic nerve, thereby prolonging the postsynaptic response to DA release (Nestler, 2005). The neurotransmitter 5-HT regulates mood and selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine and citalopram are highly specific inhibitors of the 5-HT transporter, thereby increasing the duration of 5-HT's presence in the synaptic cleft and are used in the treatment of depression (Vaswani *et al.*, 2003).

Postsynaptic Receptors/Ligand-Gated Ion Channels

The postsynaptic effect of neurotransmitter release is mediated by two classes of ligand-binding receptors, ionotropic and metabotropic receptors. The binding of neurotransmitter to ionotropic receptors lowers the transitional energy barrier

allowing for gating of the channel to occur. Once activated, permeable ions are allowed to pass across the neuronal membrane along their electrochemical gradient. The major classes of ionotropic neurotransmitter-gated channels are the superfamilies of tetrameric Glu receptors (GluR) (Kumar and Mayer, 2013) and the pentameric ligand-gated ion channel superfamily (pLGIC, also referred to as Cys-loop receptors), such as the nicotinic AChR, GlyR, GABA_AR, and 5-HT₃R (Corringer *et al.*, 2012). Metabotropic receptors mediate postsynaptic responses to neurotransmitter release by activation of G-protein signaling pathways (Katritch *et al.*, 2013). These responses are slower, but may profoundly influence cellular metabolism via transcriptional and translational regulation. Members of the muscarinic AChR (mAChR), GABA_BR, 5-HT₂R, norepinephrine, epinephrine, histamine, dopamine, neuropeptide, endocannabinoid, as well as metabotropic GluR are examples of G-protein coupled receptors.

As described previously, ligand-gated ionotropic receptors can be either excitatory or inhibitory depending on their ion permeability and the electrochemical gradient of the permeate ion. Typically, excitatory receptors are permeable to Na⁺ and K⁺ (and Ca²⁺ as is the case for the N-methyl-D-aspartate (NMDA) subtype of GluR and 5-HT₃ subtype of serotonin receptor upon activation. Activation of these receptors tends to depolarize the membrane potential, increasing the possibility of action potential generation. In mammals, the majority of excitatory neurotransmitter consists of ionotropic receptors for ACh, Glu, and 5-HT. Inhibitory receptors are permeable to Cl⁻ under cellular conditions that result in Cl⁻ influx, leading to further hyperpolarization of the membrane potential, thereby making it more difficult in reaching the threshold for action potential generation. Inhibitory neurotransmitter receptors contain members of the GlyRs and GABA_ARs (Bowerly and Smart, 2006). It should be noted that these receptors may also be excitatory under certain cellular conditions. For example, as described previously, during development activated GlyRs and GABA_ARs are excitatory due to an increased [Cl⁻]_{int} in immature neurons provides an electrochemical gradient that drives Cl⁻ efflux rather than influx (Laube *et al.*, 2002; Kirsch, 2006; Avila *et al.*, 2013).

Allosteric Effectors

The ion channels, receptors and transporters involved in action potential generation and propagation that are described in this chapter are highly allosteric large macromolecular complexes embedded in the membrane. As such, their activities may be modulated by local lipid composition, posttranslational modifications, hormones, modulatory ligands, metals (e.g., Zn²⁺), redox conditions, and other effectors such as drugs. Much of our knowledge of these molecules was predicated on the discovery of inhibitors, both specific and general, found in venoms of snails, spiders, scorpions, and snakes, amongst other organisms (Terlau and Olivera, 2004; Kularatne and Senanayake, 2014). Given the wide array of compounds that modulate activities and the wide diversity of proteins involved in neuronal signaling, we have chosen to focus the discussion on a single subclass of receptors involved in the generation of action potentials. The remainder of this section will briefly

review allosteric effectors involved in modulating the activity of inhibitory pLGICs (Corringer *et al.*, 2012), given the importance of these channels as therapeutic targets (Lynch and Callister, 2006; D'hulst *et al.*, 2009).

Inhibitory ligand-gated receptors in the adult are gated by the neurotransmitters GABA and Gly and are permeable to Cl⁻. It should be mentioned that Gly also has excitatory actions as a co-agonist at the NMDA subtype of GluRs (Johnson and Ascher, 1987). Under typical conditions in adults, the reversal potential for Cl⁻ (E_{Cl}) is approximately -70 mV, which is usually more negative than the neuronal resting potential (~ -65 mV). As a result, activation of GABA_AR or GlyR results in Cl⁻ influx, resulting in hyperpolarization of the membrane potential, making it difficult for action potentials to be generated. In cases where the neuronal resting potential is equal to E_{Cl} activation of Cl⁻ permeable channels will not hyperpolarize the membrane potential but acts to keep the potential near E_{Cl} thereby limiting the amplitude of EPSPs and decreasing the probability of action potential generation. This process of inhibition through increasing the membrane conductance is referred to as shunting.

GABA_ARs mediate a majority of inhibitory neurotransmission in the brain and spinal cord while GlyRs are mostly localized to the spinal cord, brain stem, caudal brain, and retina (Laube *et al.*, 2002). As briefly described previously, this subset of pLGICs, which also contains the excitatory nAChR, and 5-HT₃R, are pentameric assemblies, often heteromers comprised of multiple gene products, arranged quasi-symmetrically around a central pore. Each subunit contains an N-terminal ligand-binding extracellular domain (ECD) with a conserved Cys-disulfide loop (the source of their alternate nomenclature of Cys-loop receptor superfamily), four transmembrane segments (M1–M4) and a C-terminal extracellular tail (Hibbs and Gouaux, 2011). The M2 segments line the pore, and in GABA_AR and GlyR these pore-lining regions contain positively charged amino acids (at physiological pH) at critical sites that impart anion selectivity (the pore is wide enough for hydrated ions, and while broadly anion-specific, under physiological conditions primarily conducts Cl⁻ current). Three GABA_AR subunit isoforms (α , β , and γ) combine in various stoichiometries to form most of the GABA_AR in the mammalian brain, however, other isoforms exist (σ , ϵ , π , θ , and ρ). The most common GABA_AR type in the brain is comprised of 2 α , 2 β , and 1 γ subunit. An important modulator of GABA_ARs, benzodiazepines, is believed to bind between the α and γ subunits. GlyRs are formed by only two subunit isoforms, α and β . The subunit composition of each type of receptor modulates functional characteristics such as ligand affinity, gating kinetics, and channel conductance. In all pLGICs, the neurotransmitter binding site is located between adjacent subunits in their ECD (Lynagh and Pless, 2014).

Barbiturates, benzodiazepines, neurosteroids, ethanol, and inhaled anesthetics are all positive allosteric modulators of GlyRs and GABA_ARs. Given their inhibitory role, increasing the activity of these receptors can result in sedative hypnotic, anxiolytic, and muscle relaxant effects. The variety and extent of effects experienced by these inhibitory receptor targeted drugs is likely mediated by the differential subunit composition of pLGICs. These modulatory effectors bind to sites that are distinct from the neurotransmitter binding site

and their activities, in part, are due to their preferential affinity to and stabilization of different allosteric states of their receptor targets (Taly *et al.*, 2009; Corringer *et al.*, 2012). For example, the binding of phenobarbital to GABA_ARs does not directly activate the receptor, but potentiates activity of GABA bound receptors by altering channel properties such as the channel's mean open time. Inhibitors of GABA_ARs exist, however, they are therapeutically less useful due to anxiety-inducing and convulsant effects. The convulsive alkaloid strychnine, is a highly specific and potent inhibitor of adult GlyRs (it does not bind to neonatally expressed GlyRs) that is fatal in high doses, but is a performance enhancer at very low concentrations.

The inhibitory role of pLGICs has been exploited by Lester and colleagues to express transgene insect homologs in sections of the brain to study the effect of targeted neuronal silencing (Slimko *et al.*, 2002). These studies utilized a homologous insect GluCl, a Glu-gated Cl⁻ channel that is gated by ivermectin. Recently the structure of this protein has been resolved (Hibbs and Gouaux, 2011), and its structure is highly conserved to that of other bacterial pLGICs whose structure had been determined (Hilf and Dutzler, 2008; Bocquet *et al.*, 2009; Hilf and Dutzler, 2009). Given that GlyRs mediate inhibition of signals in the spinal cord and brain stem, they are attractive candidates for treating pain. Transgene expression of human GlyR in peripheral nerves using neurotrophic Herpes simplex virus engineered to express the $\alpha 1$ subunit of GlyR was shown to be effective in reducing pain in animal studies (Goss *et al.*, 2011). More recently, mutant forms of human GlyR that are activated by low levels of ivermectin, an approved FDA drug with limited off-site targets at low concentrations in mammals, has been characterized (Lynagh and Lynch, 2010), and these studies suggest that one may potentially utilize transgene expression of inhibitory pLGICs to selectively inhibit targeted neurons that may be safely activated via systemic delivery of low levels of ivermectin.

Glossary

ABC transporter A superfamily of proteins comprised of 2 membrane domains and 2 highly conserved adenosine triphosphate (ATP)-binding cassettes. Energy from ATP hydrolysis is used to move peptides, polysaccharides, signaling molecules, drugs, and ions across the cell membrane.

Airway surface liquid (ASL) A thin layer of aqueous fluid and mucus covering the airway surface between the airway cells and the air space. Important in mucociliary clearance and bacterial killing. The height of the ASL is considerably reduced in cystic fibrosis.

Apical membrane A subdomain of the plasma membrane on the apical side (the region of the membrane facing the lumen or space) of epithelial cells in a body tube or cavity, separated from the basolateral domain by tight junctions. Typically bearing micro-villi and forming the membrane across which secretion occurs.

Basolateral membrane A subdomain of the plasma membrane adjacent to the basement membrane in

epithelial cells. Separated from the apical membrane by tight junctions. The sodium pump is always found on the basolateral membrane.

Corrector A class of CFTR drugs that act to facilitate exit of mutant CFTR from the endoplasmic reticulum for traffic to the cell surface.

Ivacaftor Ivacaftor, trade name Kalydecoc, developed by Vertex Pharmaceuticals as VX-770, is a CFTR potentiator drug approved for the treatment of cystic fibrosis patients with the specific G551D mutation. Ivacaftor is N-[2,4-Bis (1,1-dimethylethyl)-5-hydroxyphenyl]-4-oxo-1,4, dihydroquinoline-3-carboxamide.

Mucociliary clearance The clearance of mucus, bacteria, and other debris from the airways by unidirectional beating of airway cell cilia.

Potentiator A class of CFTR drugs that act to increase the activity of mutant CFTR proteins that reach the cell surface.

Introduction

The finding of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene in 1987 was a landmark in human genetics, and represented the first gene ever identified or sequenced without any knowledge of its protein product (Kerem *et al.*, 1989; Riordan *et al.*, 1989; Rommens *et al.*, 1989). The discovery of the gene caused a major paradigm shift in cystic fibrosis (CF) research, culminating in the discovery and marketing of the first drug to treat the basic defect in CF (McPhail and Clancy, 2013). Research into CF continues to have a marked impact upon many areas of biochemistry, cell biology, and physiology, providing new insights into normal and disease processes. Moreover, in the years since the first description of CF as a unique disease in 1938 (Anderson, 1938), when it was unusual to see a child live past 5 years of age, there has been a dramatic increase in survival such that many patients are now living into their 3rd and 4th decades of life (Moskowitz *et al.*, 2008; Proesmans *et al.*, 2008). Much of the research in CF would not have been possible without the steadfast support of the Cystic Fibrosis Foundation (CFF, see Relevant Websites section). Indeed, the clinical availability of drugs like 'Ivacaftor' would have likely taken considerably longer without research funds from the CFF. As we gain a greater understanding of how mutations in *CFTR* lead to CF disease, we will not only learn more about basic biology, but will also provide clinicians with more therapeutic options as we move into the exciting arena of pharmacogenetics and patient care based upon the individual patient's genotype.

Key Highlights

- CF is caused by mutations in the *CFTR* gene.
- The protein coded by *CFTR* gene functions as a regulated anion channel in many epithelial cells, including the airways, pancreas, intestine, and reproductive tracts, where it regulates salt, fluid, and pH homeostasis.
- Absence or dysfunction of CFTR protein leads to marked lung disease, as well as disruption in the function of the pancreas and other organ systems.
- Patients with CF have characteristically high levels of salt (sodium chloride) in their sweat.

Protein

CF is caused by mutations in the *CFTR* gene. The *CFTR* gene encodes a protein that functions as a regulated anion channel in epithelial cells, transporting negatively charged ions such as chloride (Cl^-), and bicarbonate (HCO_3^-). *CFTR* is a member of a large family of transport proteins, called the adenosine triphosphate binding cassette (ABC) proteins that are expressed in a wide-range of phyla from yeast to human (Higgins, 1992; ter Beek *et al.*, 2014). *CFTR*, however, is only expressed in vertebrates, and is the only known ABC transporter to function specifically as an ion channel. Mutations in ABC transporter family members are linked to many human diseases in addition to CF, including Stargardt macular dystrophy (Allikmets *et al.*, 1997), Tangier disease

(Rust *et al.*, 1999), and Adrenoleukodystrophy (Morita and Imanaka, 2012).

The CFTR channel is a large multidomain membrane glycoprotein with two similar halves (Figure 1(a)), comprised of 1480 amino acids and a calculated molecular mass of 168 kDa. It consists of two, six member, transmembrane domains (TMD1 and TMD2), 2 nucleotide binding domains (NBD1 and NBD2), and, unique among ABC transporters, a regulatory (R) domain (Riordan *et al.*, 1989). Present in the extracellular portion of the protein, in TMD2, are 2 sites

for that attachment of N-linked (asparagine) carbohydrate units (Figure 1(a)). The role of the carbohydrate on CFTR is still not certain. CFTR lacking sugar residues goes to the cell surface, and functions as an ion channel in the same way as sugar containing CFTR (Chang *et al.*, 2008), however the sugar residues may impart protein stability at the cell surface, preventing premature protein degradation. Although the crystal structure of CFTR has not yet been determined, structures for domains of CFTR are available, which, along with homology mapping against known structures of similar proteins, gives

Figure 1 (a) Model showing the domain structure of CFTR. The protein has 1480 amino acids, with both the amino and carboxy termini within the cell cytoplasm. The two membrane spanning domains each contain six transmembrane segments, forming the ion channel. There are six extracellular loops. And glycosylation occurs on asparagine residues at two sites on extracellular loop 4. Also shown are two nucleotide binding domains (the $\Delta F508$ mutation is located in NBD1). Phosphorylation of the regulatory (R) domain is necessary for channel function. (b) Homology model of CFTR based on the ABC transporter Sav1866. The R domain is largely unstructured. Reprinted with permission from Serohijos, A.W., Hegedus, T., Aleksandrov, A.A., *et al.*, 2008. Phenylalanine-508 mediates a cytoplasmic-membrane domain contact in the CFTR 3D structure crucial to assembly and channel function. *Proceedings of the National Academy of Sciences of the USA* 105 (9), 3256–3261.

rise to the likely structure seen in [Figure 1\(b\)](#). The 2 nucleotide binding domains come together to form a pocket for adenosine triphosphate (ATP) binding and hydrolysis, which serves to regulate the gating (opening and closing) of the CFTR channel. The R, or regulatory, domain is mostly unstructured, but possesses multiple consensus phosphorylation sites for protein kinases. The R domain must be phosphorylated by cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA) in order to conduct chloride ions ([Riordan, 2008](#)).

CFTR and Protein Trafficking

During its life, CFTR undergoes several trafficking pathways, taking it through various cellular compartments ([Figure 2](#);

[Ameen et al., 2007](#)). Following gene transcription, the mRNA coding for CFTR leaves the nucleus and interacts with ribosomes associated with the endoplasmic reticulum (ER). As the various domains of CFTR are synthesized, the protein starts to fold and achieve its final three-dimensional conformation. CFTR is helped in its folding by a set of proteins, called chaperones, that bind and release CFTR, as CFTR tries to achieve its correct structure. Once CFTR has achieved its final conformation, all the chaperones disengage from CFTR. It takes 7–8 mins for a single CFTR molecule to be made at the rate at which most proteins are made. CFTR folds in a surprisingly inefficient manner, with over half of wild-type CFTR molecules unable to achieve their final appropriate conformation. As well as helping proteins fold, chaperones also form part of the cell's quality control machinery. CFTR molecules that are unable to fold properly remain bound by

Figure 2 Trafficking pathways for wild-type and $\Delta F508$ CFTR (i) CFTR is translated in the endoplasmic reticulum (ER) where core sugars are added to the protein. Most $\Delta F508$ is recognized as misfolded and subject to proteasomal degradation (v). Wild-type CFTR traffics to the TGN where the core sugars are modified into complex carbohydrates, and then trafficked to the apical plasma membrane (i). (ii) CFTR is efficiently removed from the cell surface by clathrin-mediated endocytosis using trafficking signals embedded in the amino acid sequence of CFTR. (iii) From endosomes, CFTR can recycle back to the cell surface in a direct manner, or via recycling endosomes. (iv) Internalized CFTR can also be directed to lysosomes for degradation. Modified from Ameen, N., Silvis, M., Bradbury, N.A., et al., 2007. Endocytic trafficking of CFTR in health and disease. *Journal of Cystic Fibrosis* 6 (1), 1–14.

chaperones, which then recruit enzymes to tag misfolded CFTR with the small protein ubiquitin. Ubiquitin acts as a signal for degradation, leading to digestion of aberrant proteins by the proteasome. CFTR also undergoes co-translational modifications in the ER, with two small sugar units added initially to asparagine residues in the fourth extracellular loop. This is referred to as 'core-glycosylated' or 'Band B' CFTR.

Once folded and core-glycosylated in the ER, acidic sequences within CFTR interact with coat protein complex II (COPII). This highly regulated process generates COPII coated vesicles that facilitate the transfer of CFTR from the ER to the Golgi complex. In the Golgi CFTR undergoes its final processing, with the conversion of the small mannose-rich core sugar units on the fourth extracellular loop to a complex highly branched carbohydrate moiety. The addition of a large number of sugar residues to CFTR in the Golgi causes a marked increase in the molecular weight of CFTR to around 180 kDa, yielding 'mature' or 'Band C' CFTR. Bands B and C can be readily visualized by Western blot analysis of cells expressing CFTR.

In the final layers of the Golgi (*Trans* Golgi Network (TGN)), CFTR associates with another coat protein, clathrin, to enter clathrin coated vesicles (CCV) for the journey from the Golgi to the cell surface. Since CFTR is a protein expressed in epithelial cells, not only must CFTR be targeted to the plasma membrane, but it must be targeted specifically to the apical or luminal plasma membrane. The one exception is the sweat duct cell (see below) that expresses CFTR in both the apical and basolateral membranes. Once in the membrane, CFTR can be activated by kinases, allowing conduction of anions. CFTR does not stay in the plasma membrane for a long time, but turns over at a rate of 10% per minute. The carboxyl tail of CFTR contains a tyrosine-based endocytosis signal that drives CFTR into endocytic CCV (Weixel and Bradbury, 2000, 2001). Once internalized, most CFTR is rapidly recycled back to the cell surface (Picciano *et al.*, 2003), where it can again function as an anion channel. CFTR molecules will undergo several rounds of internalization and recycling before being degraded; with a half life of between 12 and 24 h. Why CFTR undergoes constant internalization and recycling back to the cell surface is still not entirely clear. However, it may be a means of fine-tuning the exact amount of functional CFTR at the cell surface. For example, the rates of CFTR endocytosis and CFTR recycling can be modified by agonists. This is particularly evident in the intestine, where CFTR can move from a predominantly intracellular location to a marked cell surface location (Golin-Bisello *et al.*, 2005).

Cystic Fibrosis Is an Ion Transport Disease

Before CFTR was cloned, and before the function of CFTR was established, work by Paul Quinton in the 1980s showed for the first time that there was an underlying defect in ion transport across the epithelia of patients with CF. Quinton went on to show that, in fact, the defect was in an inability of CF patients to move chloride ions (Quinton, 1983). Interestingly, the initial cloning of the *CFTR* gene suggested that it might be a regulator of a chloride channel rather than a chloride channel itself; hence the name 'conductance

regulator.' However, within 2–3 years of *CFTR*'s cloning, definitive proof that CFTR itself could conduct chloride ions was provided (Anderson *et al.*, 1991; Bear *et al.*, 1992). More recently it has been shown that CFTR can also conduct bicarbonate ions (Bridges, 2012; Quinton, 2010), and this process is particularly important in the secretion of a bicarbonate-rich fluid from the exocrine pancreas (Steward *et al.*, 2005). Thus, CFTR is more properly described as an anion channel rather than a chloride channel.

CFTR and Chloride Transport

Since CFTR is an ion channel, the direction of ion movement through the channel depends on the direction of the anion chemical gradient across the cell. As anions also carry an electric charge, their movement is also influenced by the magnitude of electrical gradients across the membrane. The net direction of ion flow is therefore a net effect of chemical and electrical gradients. Using chloride as an example, this means that in some cell types CFTR mediates the movement of chloride out of the cell, whereas in other cells types, CFTR mediates the movement of chloride ions into the cell. In secretory epithelial cells, such as the airways, intestine, and pancreas, CFTR causes chloride ions to leave the cell. Shown in Figure 3 is a model for chloride secretion, and relies on the separation of different transport proteins between apical and basolateral membrane domains. Chloride is brought in from the blood supply across the basolateral membrane through the concerted actions of three separate transport proteins: (1) an Na-K pump, (2) an Na/K/2Cl cotransporter, and (3) a potassium channel. The basolateral Na-K pump generates an inward Na gradient, providing the driving force for uptake of chloride by the Na/K/2Cl cotransporter. The net result is a raised intracellular chloride concentration, sufficiently high that the chloride electrochemical gradient favors passive chloride exit through activated CFTR. In order to maintain efficient apical chloride efflux, basolateral potassium channels must remain active allowing potassium exit and maintaining the electrical driving force for chloride to leave through CFTR. A consequence of luminal chloride is the generation of a more lumen negative electrical potential, which promotes voltage driven Na^+ transport from the blood, through the tight junctions, into the lumen. Sodium chloride in the lumen generates an osmotic gradient allowing water flow from the blood into the lumen. In this manner, CFTR underlies the net movement of salt and water into the lumen. This kind of transport can be seen in sweat glands, salivary glands, intestinal crypts, exocrine pancreatic acini, and airways.

Normally the stimulation of chloride and fluid secretion helps hydrate the airways, and flushes out mucus from specialized glands in the airways so that a thin film of mucin lines the airways where it can trap particles of dust, bacteria, and viruses, allowing the conducting airways to remain sterile. The thin layer of mucin lies on top of a fluid layer that bathes the cilia of cells lining the airways (Figure 4). Under normal conditions, there is a balance between fluid secretion and fluid absorption (under the control of CFTR) that permits just the right height of airway surface liquid (ASL), facilitating the beating of cilia and the movement of mucin-trapped debris out of the airways. In patients with CF, the absence of CFTR

Figure 3 Model for CFTR-dependent chloride secretion.

Figure 4 Airway cilia from normal and CF patients. Electron micrographs of airway cells grown in culture from normal and CF patients. The ASL height from normal cells is $\sim 7 \mu$, allowing the cilia to beat and remove debris. In the CF cells, the ASL height is dramatically reduced, and thick dehydrated mucus helps compress the cilia so that they can no longer beat. Modified from Boucher, R.C., 2007. Evidence for airway dehydration as the initiating event in CF airway disease. *Journal of International Medical Research* 261 (1), 5–16. © Wiley.

leads to an imbalance between fluid secretion and fluid absorption, resulting in insufficient amounts of ASL. This causes the collapse of the cilia and an inability of the cilia to expel the mucin-trapped debris from the airways. In addition, the lack of fluid secretion when mucin is released means that the mucins are not properly hydrated and form a sticky viscous aggregate that is hard to dislodge. Since the mucins are not moved out of the airways, trapped bacteria rapidly grow and multiply, leading to chronic lung infections. Characteristic of CF lung disease is the presence of *Pseudomonas aeruginosa* and *Staphylococcus aureus* infections. These infections are typically gained early on in life, and once infected, CF patients are unable to eradicate the infections despite aggressive antibiotic therapy. Chronic lung infections and heavy mucus production cause airway obstruction and eventual lung destruction.

In addition to helping flush out mucins from glands just below the airway surface, fluid secretion from the salivary

glands and exocrine pancreas helps flush out digestive enzymes into the mouth and small intestine respectively. Fluid is also secreted into the intestine to help move and solubilize food through the intestine, so that it can be properly digested. In the case of intestinal crypts, little chloride is secreted under resting (i.e., unstimulated conditions) because apical CFTR chloride channels are closed. Chloride secretion requires activation of CFTR through phosphorylation of CFTR's R domain. CFTR activity can be increased by gut hormones such as vasoactive intestinal peptide, which binds to membrane receptors and activates adenylyl cyclase to raise intracellular cAMP and stimulate cAMP-dependent protein kinase (PKA). Interestingly, this pathway can be activated by bacterial toxins. Cholera toxin permanently activates adenylyl cyclase, leading to chronic activation of CFTR-mediated chloride and fluid secretion. Untreated, the amount of salt and fluid lost by a patient suffering from cholera will result in the death of the patient within a few days.

Folklore, Heat Waves, and a Diagnostic Test

Early European folklore stated, "Woe to that child which when kissed on the forehead tastes salty. He is bewitched and soon must die." Thus from early times there has been a tight association between salty sweat and high morbidity and mortality. Although a salty brow is one of the more benign manifestations of CF, the discovery of the underlying cause of salty sweat by Paul Quinton marked the start of modern CF research. Sweating on a hot day is an important mechanism that the body uses to cool down. Evaporation of water from the surface of the skin requires energy in the form of body heat. So as the sweat evaporates, the body is cooled down. In order for this cooling process to work efficiently, the sweat arriving on the surface of the skin should not be very salty. In the summer of 1949, an unusually intense heat wave hit New York City. At this time, Dorothy Andersen, who was the first to recognize CF as a genetic medical disease, was working as a physician at Columbia Presbyterian Medical School. She noted that a number of her patients (with the newly diagnosed condition of CF) were stricken with heat prostration (overheating of the body and dehydration). Paul di Sant'Agnese, a young physician working with Andersen ascribed the patients' dehydration to excess loss of salt, and identified the sweat glands as the source of that loss.

Understanding how sweat is generated provided the first clues to understanding what goes wrong in patients with CF. The sweat gland is divided into two components: the secretory coil embedded in the dermis of the skin that generates the 'primary' fluid, and a sweat duct that modifies the primary fluid, removing most of the salt from the fluid before it reaches the skin surface. The generation of an isotonic 'salty' fluid by the secretory coil essentially follows the mechanisms described above for salt and fluid secretion; requiring a sodium pump, $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ co-transporter and a K^+ channel on the basolateral membrane, and CFTR in the apical membrane (Figure 5). Sodium and water follow chloride into the lumen of the secretory coil to create a 'primary fluid.' As fluid is secreted into the lumen of the coil, hydrostatic pressure forces the primary fluid up a duct or tubule onto the surface of the skin. As sweat moves up the duct, salt is selectively removed from the fluid. Since the ducts are highly impermeable to water, water cannot follow the salt, and so a hypotonic 'salt-reduced' fluid reaches the surface of the skin where it can evaporate and cool the body. The arrangement of transport proteins in sweat duct cells is different from that of the secretory coil, consistent with the duct cells being an absorptive cell type and the coil cells having a secretory phenotype. Chloride enters the cell through apical CFTR channels and, unique to sweat duct cells, also exits the cell through basolateral CFTR channels. The absorption of chloride ions raises the driving force for the absorption of sodium ions through apical membrane sodium channels, and the exit of sodium from the cell through the sodium pump. The problem in CF is an inability of the sweat duct to absorb chloride ions, due to the absence of CFTR. Since chloride is not absorbed, there is no driving force for sodium absorption, and so both sodium and chloride ions stay in the sweat and appear at the skin surface. The high levels of salt in the sweat lead both to poor sweat evaporation and to excess salt loss from the body.

The high levels of salt in the sweat of CF patients is diagnostic for the disease (Figure 6). Early methods to collect sweat involved 'thermal stress,' either by placing the patient in a heated room (90 °F/32.2 °C) for 1–2 h, or by having the patient wear a plastic body bag and wrapped in blankets for 1–2 h. Although this latter method was widely adopted, it was not without risk, and one fatality was reported using this approach.

The question arises then, that if CF duct cells cannot absorb chloride due to the absence of CFTR, how does the secretory coil generate any primary fluid in the absence of CFTR? The answer lies in the observation that some secretory coil cells also express a calcium-activated chloride channel that can be activated by cholinergic agonists. The cholinergic agonist pilocarpine is used to stimulate sweat production in the 'CF Sweat Test'. Other secretory coil cells express adrenergic agonists that raise intracellular cAMP, leading to the activation of CFTR and the generation of adrenergic-induced sweat. In patients with CF, the adrenergic pathway is ineffective due to the absence of CFTR, but the cholinergic pathway is intact. It is the stimulation of this cholinergic pathway to increase sweat, that forms the basis for the modern 'sweat test.' Despite the ability to perform genetic screens for CFTR mutations, elevated sweat chloride remains the gold standard for the diagnosis of CF disease. A sweat chloride level of ≥ 60 mM is diagnostic of the disease (Figure 6). The level of sweat chloride generally follows the severity of disease, such that patients with milder CF disease generally have lower sweat chloride levels than those who have severe disease.

CFTR and Bicarbonate Transport

The exocrine pancreas produces and releases a large volume of alkaline fluid into the intestine to neutralize acid released from the stomach, and to raise the pH of the intestine lumen to the alkaline pH optimum required for pancreatic enzymes. The pH of the exocrine pancreatic fluid from patients with CF is significantly less alkaline than that of exocrine pancreatic fluid from non-CF individuals. The reduced pH of pancreatic secretions in patients with CF causes the acidity of the stomach contents to be incompletely neutralized once they enter the small intestine. Pancreatic enzymes, particularly lipases, are extremely sensitive to pH, and only breakdown substrates when the pH in the small intestine is sufficiently alkaline. In most CF patients, the pancreatic juice is not alkaline enough and lipases, for example, are inactive in the small intestine. This results in malabsorption of fats, poor weight gain and greasy foul-smelling stool (steatorrhea). In addition to reduced production of alkaline pancreatic juice, lack of CFTR also impedes the production of fluid required to flush out enzymes from the exocrine pancreas. This means that digestive enzymes are not flushed out of the pancreas into the intestine, leading to blockage of the ducts exiting the pancreas and causing autodigestion of the exocrine pancreatic tissue. Although generally not initially affected, the endocrine pancreas can eventually be destroyed, leading to CF related diabetes (CFRD).

CFTR plays both an indirect and a direct role in the generation of an alkaline pancreatic fluid. Similar to the sweat

Figure 5 The eccrine sweat gland is composed of a secretory coil that generates an isotonic primary fluid. The secretory coil is permeable to water. The reabsorptive duct absorbs sodium and chloride from the sweat in excess of water, due to the high water impermeability of the duct cells, leading to a hypotonic sweat on the surface of the skin. Different arrangements of transport proteins in the coil and duct cells allow coil cells to perform a secretory function and duct cells to perform an absorptive function.

gland, the distal portions of the exocrine pancreas (the acini, which also secrete the digestive enzymes) secrete a 'primary fluid' with a similar ionic composition to the plasma. The mechanism by which the primary fluid is generated in the pancreas is identical to that in the intestine and the sweat gland secretory coil. As the fluid moves down the pancreatic ducts, it is modified to produce a final bicarbonate (HCO_3^-)-rich ($\sim 140 \text{ mM}$) alkaline fluid. In contrast to the sweat ducts where sodium and chloride ions are both absorbed to yield a hypotonic fluid, the pancreatic ducts gradually replace

the chloride ions with bicarbonate ions. How this is achieved depends on where it occurs within the pancreatic duct (Figure 7). In the proximal region of the duct, CFTR functions as a chloride channel allowing exit of chloride into the lumen of the duct. This chloride re-enters the cell using a chloride-bicarbonate co-transporter, which brings chloride into the cell in exchange for the exit of bicarbonate into the lumen. The more distal regions of the pancreatic duct lack a chloride-bicarbonate exchanger, and in this region bicarbonate exits the cell directly through CFTR. Therefore in the proximal duct

region, CFTR is a chloride channel, but in the distal duct region, CFTR is a bicarbonate channel. It can easily be appreciated that loss of CFTR channel activity will not only lead to a reduced production of primary fluid, but also an inability to properly alkalize the pancreatic fluid. The lack of an alkaline fluid or digestive enzymes was once a major cause of morbidity in patients with CF; many patients dying of malnourishment. The advent of pancreatic enzyme supplements that can be taken with food has alleviated many of the

problems of malnutrition, such that lung disease is now the major cause of morbidity and mortality in CF patients. However, the digestive process is still inefficient and many CF patients require high calorie diets and still have problems associated with impaired lipid digestion.

Genetics

CF is an autosomal recessive disease, so affected individuals must inherit one *CFTR* mutation from each parent in accordance with classical Mendelian genetics. Parents who are heterozygous generally do not display any clinical phenotype. The gene for *CFTR* is located on the middle of the long arm of chromosome 7 (at 7q31.2). The *CFTR* gene contains at least 27 exons (coding regions) and encompasses ~250 kb of DNA. The gene is transcribed into a mature mRNA of 6.5 kb. *CFTR* gene expression is highly regulated, being confined to certain tissues and displaying cell-type specificity. The incidence of CF is 1 in 2000 to 3000 live births among Caucasian populations, giving a carrier frequency of around 1:25. Although *CFTR* gene mutations associated with disease are most prevalent in populations of European descent, mutations have been detected in other ethnic groups. Despite the discovery of approximately 2000 different disease causing mutations in the *CFTR* gene, fewer than 10 account for nearly all the mutations observed in US patients with CF. The most common mutation

Figure 6 Stimulated chloride concentration (mM) in sweat from non-CF and CF patients. Sweat chloride concentrations above 60 mM are considered diagnostic for CF.

Figure 7 Production of alkaline pancreatic fluid. The pancreas secretes 140 mM NaHCO_3 solution. The mechanism for secretion of HCO_3^- depends on the section of the pancreatic duct. Close to the production of the acinar primary fluid, CFTR works in concert with a $\text{Cl}^-/\text{HCO}_3^-$ exchanger with chloride exiting the cell through CFTR. In distal portions of the duct, HCO_3^- exits directly through CFTR. R117H CFTR shows impaired Cl^- transport through CFTR, with a much smaller effect on HCO_3^- transport through CFTR.

Figure 8 CFTR resides on chromosome 7. The defect that most often leads to cystic fibrosis is the deletion of three nucleotides from the gene. This mutation ($\Delta F508$) results from the loss of one amino acid – phenylalanine at position 508– in the CFTR protein. Although there is a loss of two base pairs from one codon and one base pair from another codon, the remaining triplet ATT is an alternative codon for isoleucine. The mutant protein still has isoleucine at position 507, followed by the GGT sequence for the glycine that would normally follow phenylalanine.

is the loss of a phenylalanine residue at position 508 ($\Delta F508$, also called *F508del*) and accounts for over two-thirds of all disease causing alleles in patients with CF; indeed 90% of CF patients have at least one $\Delta F508$ allele (Figure 8). Other common mutations include G551D, G542X, W1282X, and N1303K. With around 2000 mutations, many of which only appear in one family, it can be appreciated why the sweat test remains the gold standard for diagnosis. Despite the numerous mutations giving rise to the clinical symptoms associated with CF, all mutations can fall into two basic categories: mutations that affect the quantity of CFTR, and mutations that affect the quality of CFTR at the cell surface.

Mutations in CFTR

Given the number of possible mutations giving rise to CF, it is not surprising that different mutations can affect CFTR function in different ways and in different degrees (Figure 8). Even though many mutations are present only in a few patients, they nonetheless have provided insight into the workings of CFTR at the protein and cellular level. It has proven useful to classify mutations according to their functional consequences. CF-causing mutations can reduce CFTR ion transport by reducing the quantity of functional channels at the surface of epithelial cells, or by reducing the quality/function of surface CFTR as an ion channel. The degree to which either the quantity or the quality of CFTR channels is affected is reflected in the amount of anions that can be transported by CFTR, and ultimately in the severity of the disease experienced by patients

with CF. For example, mutations that severely affect protein synthesis and/or channel gating (e.g., $\Delta F508$, W1282X, and G551D) often eliminate or significantly reduce the ability of CFTR to transport anions, and are often associated with severe disease. In contrast, CF-causing mutations that only reduce protein production to a modest degree, or modestly reduce ion conductance (e.g., 3849 + 10 kb C $\rightarrow$ T, R347P) usually retain some ion transport capability. While not sufficient to maintain full/normal ion channel function, these latter mutations nonetheless are associated with much milder CF.

Mutations affecting CFTR quantity

Mutations affecting channel quantity run the spectrum from no CFTR being expressed, to a little CFTR reaching the cell surface (Figure 9). Many mutations that result in premature stop codons (e.g., G542X and R553X) yield essentially no CFTR at the cell surface. Other mutations reduce surface CFTR by producing a protein that is defective in processing or trafficking. For example, the most common mutation, $\Delta F508$, is a severe processing mutation. $\Delta F508$ is unable to achieve an appropriate stable three-dimensional structure in the ER and is targeted by the ER quality control system for degradation; resulting in little or no $\Delta F508$ CFTR at the cell surface. The lack of CFTR at the cell surface results in little or no CFTR-mediated ion transport. Certain mutations result in some CFTR reaching the cell surface. Many of these mutations occur at splice sites, resulting in inefficient splicing out of introns. The CFTR mRNA that is correctly spliced produces fully normal CFTR; however because of the splicing difficulties very

Figure 9 Categories of CF-causing mutations that result in CFTR dysfunction.

little mRNA is made. The most common example is the 3849 + 10 kb C→T mutation. Even though little CFTR reaches the surface in splice mutations, the CFTR that does reach the plasma membrane is fully normal. Although these patients may have lung disease characteristic of CF, many have sufficient levels of functional CFTR in the pancreas that allows them to retain some pancreatic function (pancreatic sufficient).

Mutations affecting CFTR quality

As an ion channel, CFTR needs appropriate gating (the ability of the channel to open and close), and appropriate conductance (the ability of ions to move through the channel). Many CFTR gating mutations result in the proper amount of CFTR being inserted into the plasma membrane, however the channel has difficulty opening or once open closes too quickly (Figure 9). These mutations are said to have a low open probability (P_o). The most common example of this type of mutation is the G551D mutation, a mutation that is present in ~5% of the CF population. Despite the presence of G551D CFTR at the cell surface, its gating defect limits the number of ions that can move through the channel. It should be noted that the $\Delta F508$ mutation also displays gating abnormalities. Thus, the $\Delta F508$ mutation affects both the quantity and quality of CFTR. Far from an academic curiosity, it means that 2 things must be corrected in $\Delta F508$ CFTR in order to provide an effective therapy for patients bearing this mutation. Mutations that alter CFTR conductance also generally result in good levels of CFTR at the cell surface, but the ability of ions to flow through the channel is severely compromised. These mutations usually occur within the pore region of the channel and restrict the number of ions able to pass through the pore. R117H and R347P are common examples of this type of mutation. As discussed, CFTR has the

ability to transport both chloride and bicarbonate ions; important especially in pancreatic function. The R117H mutation affects the ability of CFTR to conduct bicarbonate ions to a lesser degree than chloride ions. R117H CFTR allows little chloride to pass, but bicarbonate is not impeded as much. As a consequence, many CF patients with the R117H mutation retain some pancreatic function even though other characteristic features of CF, such as elevated sweat chloride, are present.

Pharmacologic Approaches to Treat Patients with CF

In 2012, the first drug was approved for the treatment of the basic defect in CF. The drug, Ivacaftor (kalydeco; Vertex Pharmaceuticals) was designed to treat gating mutations, specifically, the G551D mutation. This class of drugs, called 'potentiators' works with G551D to increase the amount of time the channel spends open and conducting ions. Since its introduction, Ivacaftor has proven to be effective for the treatment of patients with the G551D mutation, leading to a marked improvement in lung function (the most important cause of morbidity and mortality in CF patients). Clinical trials with other gating mutations are underway. Despite the success of Ivacaftor, it is currently only approved to treat those patients with the G551D mutation (~5% of the CF population). Another approach is required to help the common $\Delta F508$ mutation. Although Ivacaftor has some benefit in correcting the gating defect associated with $\Delta F508$ CFTR, the lack of $\Delta F508$ at the cell surface renders Ivacaftor ineffective on its own. Other compounds are required to allow $\Delta F508$ to bypass the ER quality control allowing $\Delta F508$ to exit the ER and traffic to the cell surface. These compounds are known as 'correctors.' Although several correctors are currently being investigated, none is yet approved for clinical use.

Introduction

Polysaccharides represent a major class of macromolecules in nature, with a wide range of structures and functions. Glucose, in contrast, is the most common of nutrients, whether as an exogenous source of energy and carbon or as a nutritional intermediate within cells or organisms. Polymers of glucose constitute only a small subset of naturally occurring non-structural polysaccharides but are almost universally present within cells, as glycogen, starch, or chemical variants thereof, where they serve as osmotically neutral repositories of metabolically accessible glucose. For millennia, starch has been produced from grains and tubers and used in a variety of human applications, but understanding its nature has taken centuries (Seetharaman and Bertoft, 2012). The first insight into its structure came in 1716 when Leeuwenhoek identified discrete starch granules. By the early 1800s, it was recognized that starch could be converted into sugars, of which glucose was identified as a component by mid-century. In the 1850s, Claude Bernard described a compound in the liver of animals, glycogen, that could be converted to glucose (Young, 1957). However, knowledge of the chemical structures of glycogen and starch in modern terms, as well as their chemical relatedness, was not complete until well into the twentieth century. The reader is directed to recent reviews of the metabolism of starch in plants (Zeeman *et al.*, 2010) and of glycogen in mammals (Roach *et al.*, 2012) and microorganisms (Wilson *et al.*, 2010).

Structures of Glycogen and Starch

Common Chemistry

Glycogen and starch are both polymers of glucose in which the main polymerizing linkages are α -1,4-glycosidic bonds

between glucose residues (Figure 1; for reviews, see Roach *et al.*, 2012; Zeeman *et al.*, 2010). Starch granules contain both amylose and amylopectin, the former an essentially linear polymer and the latter branched by the presence of α -1,6-glycosidic linkages. Glycogen resembles amylopectin in that it is also branched by α -1,6-glycosidic linkages. Glycogen and starch are both polydisperse, meaning that individual molecules are not identical due to the stochastic nature of their syntheses and so a given sample can be characterized only by population averages of properties like molecular weight, chain length, and branching frequency (ratio of α -1,6-linkages to α -1,4-linkages). Both glycogen and starch tend to be large molecules, with masses that can reach beyond 10^8 , the equivalent of $\sim 0.5 \times 10^6$ glucose residues, depending on the source. Because of the polydispersity, unique three-dimensional structures for these polysaccharides are impossible to obtain by the usual methods of structural biology but significant insights into structure have emerged. Early applications of X-ray diffraction established that starch granules produced coherent diffraction patterns consistent with a significant degree of structural organization and indeed crystallinity. The idea later evolved that polyglucose chains in starch and glycogen can form helices that are stabilized by hydrogen bonding. Although glycogen and starch are composed predominantly of glucose, other trace constituents have been reported, the most important of which is covalently attached phosphate.

Glycogen

Glycogen is cytosolic and relatively soluble, whether in single-celled organisms like yeasts and bacteria or in the organs of mammals. However, there is the potential for localization and interaction with other cellular components that can lead to its detection in insoluble fractions. The two most prominent mammalian stores of glycogen are in liver and skeletal muscle

Figure 1 Structures of glycogen and amylopectin. Both polysaccharides are polymers of glucose generated by the same chemical linkages between glucose residues. The differences are in their topologies, which are determined largely by the locations of the branch points, and the average chain lengths, which are longer in amylopectin. In glycogen, the branch points are evenly distributed, average two per inner B-chain, in a tiered structure. The outer A-chains are unbranched. In amylopectin, the branches are clustered, allowing for ordered semicrystalline regions (double headed arrows), where adjacent chains form double helices, alternating with disordered regions containing the branch points. In addition, longer chains span and connect the cluster-containing semicrystalline regions.

although other tissues can synthesize glycogen, notably heart, brain, kidney, and fat.

A current model for animal glycogen structure (**Figure 1**) envisions a fundamentally spherical structure formed of tiers of chains emanating from a single initial chain. The average chain length is typically 13 residues. Each of the inner or B-chains would carry two branch points, so that the number of chains, and hence glucoses, roughly doubles with each additional tier. As a corollary, the number of glucose residues in the outer tier will equal the sum of the glucose residues in all inner tiers. The outermost, A-chains, would be unbranched on the model. Thus, the overall branching frequency is approximately one branch per 12 glucoses. After 12 tiers, such a molecule reaches a theoretical maximum size of $\sim 55\,000$ glucose residues, $M_r \sim 10^7$ and diameter ~ 44 nm. These molecules would correspond to the so-called β -particles observed by electron microscopy in muscle, though in practice few full-size particles are present, rather a distribution with average diameter ~ 25 nm. In liver, larger α -particles are reported, possibly composed of β -particles,

although the chemical basis for the linkage between β -particles is unclear. Glycogen forms assemblages with proteins to form particles that can be isolated biochemically. The particles result from the ability of the associated proteins to bind directly to glycogen and/or to each other. Some of the bound proteins can interact with membranes to explain the observed association of glycogen particles with endoplasmic or sarcoplasmic reticulum in liver and muscle cells. Most of the glycogen-associated proteins are involved in its metabolism, either directly or by regulating other enzymes. The topology of glycogen, whereby many outer chains per molecule are available to bind enzymes for elongation or breakdown, contributes to the efficiency of its metabolism.

Starch

Starch is unique to plants and represents an evolution from a simpler, ancestral ability to synthesize glycogen. In higher

plants, starch is present as insoluble granules in leaves as well as non-photosynthetic organs such as stems, roots, tubers, and seeds. These are the parts of plants that are harvested for sustenance or as animal feed: seeds from cereals (e.g., rice, maize, wheat), tubers (e.g., potato), storage roots (e.g., cassava), and seeds of peas and beans.

Starch granules are much larger and are more complex than glycogen particles. They are formed in plastids (amyloplasts or, in photosynthetic tissue, in chloroplasts) and are composed mainly of amylopectin (>75%), the architecture of which allows for a highly organized, semicrystalline structure (Figure 1; for a comprehensive review of starch structure see Pérez and Bertoft, 2010). Amylopectin has molecular weight 10^7 – 10^9 Da with polyglucose chains ranging from six to more than a hundred residues long. An essential difference between glycogen and amylopectin is the frequency and distribution of the α -1,6-branch points. In glycogen, the chains are relatively short and branching is relatively uniform. In amylopectin, the chains are longer and the branch points arranged so that clusters of adjacent, unbranched chain segments interact to form double helices. These align and pack to form stable lamellae, which underlie the semicrystalline nature of starch (Figure 1). Semicrystalline lamellae alternate with amorphous regions containing branch points. This lamellar organization has a periodicity of 9–10 nm, which can be viewed by transmission electron microscopy and detected by X-ray diffraction. Within the clusters of amylopectin, the chain lengths are between 12 and 15 residues. Chains that span two or three clusters average 35–40 or 70–80 residues, respectively, resulting in a characteristic polymodality of chain lengths. The lesser component of the starch granule, amylose, is smaller (molecular weight 10^5 – 10^6 Da) and minimally branched. Amylose is thought to be present in amorphous regions of the granule in an unorganized form and plants lacking amylose have starch granules that appear normal. Although elements of the structure of the starch granule are quite conserved, note that there is nonetheless significant variation in the detailed structures and physicochemical properties of starches derived from different plant species and organs. As in the case of glycogen, proteins associated with starch granules and several synthetic enzymes have been proposed to act together in protein complexes during granule formation.

Function

From unicellular organisms to plants and mammals, the primary role of glycogen and starch is the storage of glucose during times of nutritional or energetic plenty for retrieval during times of deprivation. The evolution of polysaccharides as vehicles for sequestering glucose is usually attributed to the osmotic advantage of utilizing polymers, despite the energetic cost of their biosynthesis. In mammals, after feeding, ingested glucose is converted into glycogen in liver and muscle, quantitatively the two major glycogen deposits in the body. Besides maintaining stores of the polysaccharide, this conversion also serves to reduce blood glucose levels after a meal, part of the mechanism of blood glucose homeostasis. Impaired glucose handling, and elevated blood glucose (hyperglycemia), is the hallmark of diabetes, the most prevalent and threatening metabolic

disease of the twenty-first century. Liver glycogen serves primarily for the hepatic production of glucose in response to short-term fasting, to prevent blood glucose levels from dropping excessively (hypoglycemia). Some tissues, notably the brain and red blood cells, need glucose for normal function. Muscle glycogen serves as a short-term supply of energy for muscle contraction in some muscle fibers and does not directly contribute to increasing blood glucose levels.

In the leaves of plants, some of the carbon captured by photosynthesis in the day time is retained in the chloroplasts as starch instead of being converted into sucrose for export to other tissues. This so-called transitory starch is degraded at night to provide energy for the leaf and to be converted to sucrose for the rest of the plant. This partitioning of assimilates between starch and sucrose during the day is finely controlled. For example, a larger fraction of the assimilated carbon is stored as starch when the days are short than when the days are long, presumably so that sufficient carbon is available for the long nights that follow short days. Furthermore, starch is degraded gradually so that it lasts the entire length of the night. Impaired starch metabolism in leaves (e.g., in mutants lacking enzymes for precursor production) is associated with reduced growth rates of the plant (Stitt and Zeeman, 2012). In non-photosynthetic tissues (stems, roots, tubers, and seeds), sucrose translocated from the leaves is the precursor for starch biosynthesis. In these tissues, starch serves for longer-term storage, often to support specific functions such as seasonal regrowth, flowering and fruit set, or seedling development. This process could be seen as analogous to the utilization of glycogen stores during sporulation by some bacteria and yeasts.

Glycogen Metabolism

Glycogen Synthesis

As in the biosynthesis of almost all polysaccharides, the immediate sugar donor for glycogen formation is a nucleoside diphosphate sugar, usually UDP (uridine diphosphate)-glucose although prokaryotic species generally utilize ADP (adenosine diphosphate)-glucose (Figures 2 and 3). The origin of the glucose is normally from the environment of the cell although under certain special circumstances the glucose may be produced in the cell from other metabolites, for example, from lactate, pyruvate, alanine, or other amino acids in mammalian liver cells when transitioning from a fasted to a fed state. In eukaryotes, much of glycogen metabolism involves the growth and degradation of existing glycogen molecules. However, *de novo* synthesis of glycogen molecules can occur and sometimes glycogen molecules are completely consumed.

The current model for the *de novo* synthesis of glycogen invokes a specialized initiator protein, a unique type of glucosyltransferase enzyme, called glycogenin, that is able to transfer glucose from UDP-glucose first to a tyrosine residue on itself and then to elongate the attached glucose via α -1,4-glycosidic linkages to generate a short polyglucose chain of 8–12 residues in length. Glycogenin protein interacts directly

Figure 2 Enzyme activities involved in glycogen and starch metabolism. Synthesis of the α -1,4-glycosidic linkages of glycogen, amylopectin, and amylose is catalyzed by glucosyltransferases that add glucose from a high energy donor, ADP-glucose (starch) or UDP-glucose (glycogen) to the nonreducing ends of growing polyglucose chains. BEs are glucanotransferases that form branch points by breaking α -1,4-glycosidic linkages and reforming α -1,6-glycosidic linkages. Phosphorylases are exoenzymes that catalyze phosphorolytic cleavage of an α -1,4-glycosidic linkage at the nonreducing end of a chain to release glucose-1-P. Debranching enzymes (e.g., isoamylases) directly hydrolyze the α -1,6-glycosidic linkages of amylopectin. Glycogen is also debranched in this way in prokaryotes but in yeast and animals debranching is brought about by a bifunctional enzyme, combining glucanotransferase and amyloglucosidase activities. α -Glucosidases, including the mammalian lysosomal enzyme, can hydrolyze branched glucose polymers to glucose. BAM are exoglycosidases that release maltose units from the nonreducing ends of polyglucose chains of four residues or longer. α -Amylases are endoglycosidases that cleave α -1,4-glycosidic linkages typically in chains longer than three residues. Disproportionating enzymes are glucanotransferases that transfer maltose from the nonreducing end of a polyglucose chain to an acceptor chain. In the degradation of starch, they enable the metabolism of maltotriose to glucose and a longer glucan that is susceptible to further degradation by other enzymes. The glucan, water dikinases GWD and PWD phosphorylate glucose residues in amylopectin using ATP as the phosphoryl donor. Glucan phosphatases (SEX4, LSF1, and laforin) hydrolyze phosphomonoesters attached to glucose residues in poly- or oligosaccharides. In the figure, the colored circles represent glucose residues, red being used to identify residues transferred or cleaved. P, covalent phosphate monoester of a glucose residue.

with glycogen synthase which is responsible for the bulk polymerization required for glycogen formation. Yeasts, but not bacteria, have a similar enzyme activity. Experiments using genetically manipulated mice and yeast, however, suggest that the mechanism of glycogen initiation may be more complex than this simple model (Torija *et al.*, 2005).

Glycogen synthase adds glucose residues to the nonreducing ends of the outer chains of a glycogen molecule. Accounting for the formation of the UDP-glucose precursor from uridine triphosphate (UTP) and the subsequent hydrolysis of the PP_i produced, the cost of elongating glycogen by one glucose residue is two ATP equivalents, making synthesis energetically expensive. Branches are introduced by a branching enzyme (BE) that transfers a chain of ~ 7 glucose residues, breaking an α -1,4-glycosidic linkage and reforming an α -1,6-glycosidic linkage. Although isoforms of the biosynthetic enzymes exist in mammals, these appear to be tissue specific so that a given cell type can be totally competent for the *de novo* biosynthesis of glycogen with the presence of just three enzymes: glycogenin, glycogen synthase, and BE.

Glycogen Degradation

The breakdown of glycogen can occur via two distinct pathways (Figures 2 and 3). The cytosolic pathway requires two enzymes, glycogen phosphorylase and debranching enzyme, and is present from microorganisms to mammals. Phosphorylase catalyzes the phosphorolytic cleavage of the outermost glucose residues of the nonreducing ends to generate glucose-1-P which is either converted into glucose (liver) or fed into the glycolytic pathway for energy production (muscle). Phosphorylase cannot operate when the glucose chain is four residues or fewer from a branch point. Degradation through a branch point requires the debranching enzyme whose action eliminates the α -1,6-glycosidic linkage and generates a free glucose molecule. In a given cell, glycogen degradation requires just two enzymes. The second degradative pathway, which is best characterized in mammals, involves the transfer of glycogen molecules to lysosomes by a vesicular trafficking mechanism that likely resembles autophagy. Within the lysosome, glycogen is hydrolyzed completely by an α -glucosidase

Figure 3 Glycogen metabolism and glycogen storage diseases. The figure depicts glycogen metabolism and associated intermediary metabolism. BE, branching enzyme; DBE, debranching enzyme; GN, glycogenin; GP, glycogen phosphorylase; GS, glycogen synthase; G6Pase, glucose-6-phosphatase; LD, Lafora disease; PFK, phosphofructokinase; PGM, phosphoglucosmutase; PhK, phosphorylase kinase. Roman numerals denote the glycogen storage disease associated with mutations in the gene encoding the corresponding enzyme.

enzyme (acid maltase, GAA) to glucose that can be utilized by the cell as a source of carbon and/or energy. Yeast can similarly transport glycogen to its vacuole, the approximate equivalent of the lysosome, and degrade it as needed.

Regulation

Study of the control of the cytosolic glycogen-metabolizing enzymes in mammals has played an important historical role in the development of several key biochemical concepts of cellular regulation, namely control by allosteric ligand binding, reversible covalent phosphorylation of proteins, and hormone-mediated second messenger signaling systems. Glycogen synthase and phosphorylase are the key loci for regulation. Phosphorylation of these enzymes is promoted by the cyclic AMP (adenosine monophosphate) pathway, in the liver as a response to elevated glucagon indicative of the fasted state and in muscle as a response to elevated epinephrine indicative of increased muscular activity as in the 'fight or flight' response. Under these conditions, glycogen synthase is inactivated and phosphorylase is activated, promoting glycogen breakdown to supply either glucose (in liver) or ATP (in muscle), whilst suppressing wasteful 'futile cycling' by the coordinated control of both activities. In the fed state, insulin promotes dephosphorylation of these enzymes, thereby promoting glycogen synthesis in a similarly coordinated fashion. Glucose-6-P allosterically activates glycogen synthase and inhibits phosphorylase allowing for controls that reflect the intracellular energetic status. AMP, by activating glycogen phosphorylase, provides another intracellular regulatory input.

Glycogen Phosphorylation

Glycogen contains a small proportion of covalently linked phosphate which is present as monoesters of C2, C3, and C6

carbons of glucose residues. In contrast to starch phosphorylation, the function of the phosphate in glycogen is unclear, as is its origin. No glycogen phosphorylating enzymes, comparable to the glucan dikinases discovered in plants (see below), have been identified in mammals. One proposal that could account for C2 and possibly C3 phosphomonoesters is that phosphate is derived from a rare side reaction catalyzed by glycogen synthase in which the β -phosphate of the substrate UDP-glucose is transferred as a glucose phosphate unit rather than the normal glucose residue. However, this mechanism cannot explain the presence of C6 phosphate. Nevertheless, it is well established that glycogen phosphate is removed by a glycogen phosphatase called laforin which contains both a phosphatase domain and a glycogen-binding domain. Genetic defects in laforin lead to a serious neurological disorder called Lafora disease, strongly suggesting that controlling the level of glycogen phosphorylation is of biological importance.

Starch Metabolism

Starch Synthesis

The immediate precursor for starch synthesis in higher plants is ADP-glucose (Figure 4), although in red algae and glaucophytes some starch synthases utilize UDP-glucose. Although some aspects of amylopectin synthesis resemble those of glycogen, namely the formation of the α -1,4-glycosidic and α -1,6-glycosidic linkages, the relative topological complexity of starch is coupled to a more complicated enzymatic machinery. In higher plants, there are five gene classes of starch synthase (GBSS, SSI-IV) with distinguishable biochemical properties and two types of BE. The relative levels of these isoenzymes vary among starch-producing tissues resulting in subtle, yet significant differences in the topology of the synthesized polysaccharide.

A major difference with glycogen formation is the requirement during amylopectin synthesis of debranching enzymes that help to ensure the correct distribution and positioning of the branch points (Figures 2 and 4). Two families of debranching enzyme exist in plants, isoamylase (composed of three isoforms ISA1-3) and limit-dextrinase (LDA). Genetic impairment of one debranching enzyme activity (which contains either ISA1 subunits or ISA1 and ISA2 subunits) can lead to plants that produce a more soluble, glycogen-like polymer (termed phytoglycogen) consistent with proper debranching activity being linked to the characteristic branched structure of amylopectin. Evidence is also accumulating for the existence of complexes of amylopectin-synthesizing enzymes, with starch synthases and BEs being detected in different combinations which might orchestrate their actions to generate specific glucan structures. Although plants contain glycogenin-like proteins and other reversibly glycosylated proteins, there is so far no compelling evidence for their role in the initiation of starch synthesis comparable to glycogen initiation. Rather, some studies have suggested that specific starch synthase isoforms may themselves contribute to the initiation process. Synthesis of the amylose component of starch is mediated by granule-bound starch synthase (GBSS) which, unlike the other isoforms, is

Figure 4 Starch synthesis and degradation in *Arabidopsis* leaves. The substrate for starch synthesis, ADP-glucose, is derived from photosynthesis and the Calvin cycle during the day. The insoluble starch is produced by the coordinated activities of multiple starch synthases, BEs, and debranching enzymes. At night, the starch granule surface is disrupted/solubilized by glucan phosphorylation, followed by simultaneous dephosphorylation and glucan hydrolysis. The main exported products are the neutral sugars, maltose and glucose. Some Glc1P may be generated through phosphorolysis and used for plastidial metabolism or exported. In the cytosol, glucose and maltose are metabolized to support respiration and continued sucrose biosynthesis. exclusively localized to the starch granule and catalyzes a processive addition of glucose residues from the ADP-glucose donor. It was recently discovered that a mechanism exists to 'deliver' GBSS to the starch granule surface, via the action of a nonenzymatic, starch-binding protein.

Starch Degradation

Multiple pathways for starch degradation exist and these can differ markedly between plant organs. The processes in leaves, where starch is broken down at night, and in cereal endosperms,

where it is degraded after germination, are the best understood. In the chloroplasts of leaves, starch is converted primarily to maltose and glucose, which can be exported to the cytosol for further metabolism, including oxidative respiration and the synthesis of sucrose for export to other tissues (Figure 4). It is now believed that the first stage in starch breakdown is the covalent phosphorylation of amylopectin by a pair of dikinase enzymes which transfer the β -phosphate of ATP to form a C3 or C6 phosphomonoester of a glucose residue concomitant with the production of AMP and inorganic phosphate. These enzymes, glucan water dikinase (GWD) and phosphoglucan water dikinase (PWD), act in sequence to modify the C6 and C3 positions, respectively of different glucosyl residues of amylopectin. The idea is that the introduction of phosphate groups disrupts the hydrogen bonding and packing of the polyglucose helices in the semicrystalline regions at the granule surface, helping to solubilize the glucans. The exposed chains are then susceptible to β -amylases (BAM) which hydrolyze α -1,4-glycosidic linkages. However, BAM cannot degrade α -1,6-linkages for which debranching enzymes are required (ISA3 and LDA in *Arabidopsis*) to generate short, linear oligosaccharides. Nor can BAM degrade past phosphate residues, and these are removed by a pair of phosphoglucan phosphatases, encoded by the SEX4 and LSF2 (for Starch EXcess 4 and Like Starch excess Four 2, respectively). Study of *sex4* and *lsf2* mutants indicates that dephosphorylation of glucans is necessary for complete degradation of starch since mutation of both results in a severe starch excess (SEX) phenotype. Interestingly, these phosphatases have similarity to the laforin phosphatase that acts on glycogen in animals. Other enzymes, including the disproportionating enzymes, plastidial α -amylase and plastidial α -glucan phosphorylase are also involved in the complete degradation of starch.

The breakdown of starch in cereal endosperm occurs in a quite different environment. At seed maturity, the starchy endosperm – the dried-out tissue consisting of starch granules, storage proteins, and cell walls – is dead. After germination, the starch is degraded by enzymes either preformed in the endosperm or secreted from living parts of the seed to generate primarily glucose. This released sugar fuels the growth of the embryo. The four enzymes, α -amylase, β -amylase, debranching enzymes (specifically LDA), and α -glucosidase, are all active in the process, although the relative importance of each is not known precisely. Nevertheless, it is generally accepted that α -amylase, which is present as several isoforms, plays a central role.

Genetic Modification of Starch and Glycogen Metabolism

Genetic defects in glycogen metabolism have generally presented as rare familial diseases in humans, occasionally in domesticated animals including horses, pigs, and dogs. Many of these glycogen storage diseases (GSDs) or glycogenoses have been known for many years and have been well characterized biochemically and clinically (Chen and Burchell, 1995); however, new examples continue to be discovered (Oldfors and DiMauro, 2013). GSDs can basically be divided into two categories: mutations that directly affect the enzymes of glycogen metabolism (glycogenin, glycogen synthase, BE,

debranching enzyme, phosphorylase, lysosomal α -glucosidase, laforin) and mutations in enzymes that affect glycogen accumulation indirectly, such as via excessive accumulation of glycolytic intermediates (phosphofructokinase, phosphoglucomutase, aldolase, glucose-6-phosphatase, etc.). The number of genes implicated so far is in the twenties. Besides their clinical relevance, GSDs have proven especially important in validating the postulated functions of the glycogen-metabolizing enzymes: for example, defective BE (Andersen disease or adult polyglucosan disease) results in glycogen with a less branched structure, resembling amylopectin in some of its physicochemical properties. Defective lysosomal α -glucosidase (Pompe disease) can be fatal due to cardiomyopathy, underscoring the importance of the lysosomal pathway of glycogen degradation. Lafora disease, which is characterized by accumulation of abnormal glycogen with excessive phosphate content in deposits called Lafora bodies, is linked to loss of function of the laforin phosphatase or of malin, an E3 ubiquitin ligase of unclear function. The abnormal glycogen has devastating effects on neurons leading to neuronal cell death, a progressive myoclonic epilepsy, neurological decline, and inevitable death usually in the twenties. Though much remains to be understood about glycogen phosphorylation, its role in Lafora disease emphasizes the importance of avoiding excessive glycogen phosphorylation. While deliberate genetic manipulation of glycogen metabolism has been widely exploited as an experimental approach in mice, only now are gene therapy approaches beginning to be applied to patients though these therapies could become important in the future. Enzyme replacement therapy, in which active enzyme is administered systemically with the goal that some proportion can replace the defective endogenous protein, has already been used with some success, especially in Pompe disease.

Besides its application in scientific research, genetic manipulation of starch metabolism in plants has a whole different scope compared with glycogen, given that starch is of such major global importance, in the human diet, as animal feed, and as an industrial material, including its use as a precursor of bioethanol (see Zeeman *et al.*, 2010 and references therein). Starch from different natural sources has a wide range of polymer compositions and structures leading to significant differences in physicochemical properties, all of which could be modified genetically. However, the structural and enzymological complexity of starch poses many challenges. As a means of simply increasing starch accumulation, transgenic expression of an unregulated ADP-glucose pyrophosphorylase has had mixed success. Promoting plastid ATP production, via transgenic plastid adenylate translocase or down-regulation of adenylate kinase, does promote starch accumulation. Suppressing starch breakdown, in particular by down-regulating GWD, has successfully elevated starch yield in several plants and in potatoes has the benefit of inhibiting the generation of reducing sugars, glucose and fructose upon storage (cold sweetening) which is detrimental during frying. Enhancing the capacity for starch degradation has been applied to crops intended for ethanol production. By expressing a thermostable α -amylase in corn, and targeting it to cellular compartments not involved in starch synthesis, the enzyme does not interfere with starch production. However, upon heating corn kernels in water, the thermostable α -amylase initiates the conversion of starch to fermentable

sugars. Another broad approach is to attempt manipulation of the relative proportions of amylose and amylopectin. For example, transgenic potato and cassava plants lacking amylose have been produced. While such research – in both the academic and private sectors – has revealed the potential benefits of genetic modification in starch crops, the commercialization of such ‘GM-plants’ has stalled in many parts of the world, including Europe. This is because of the very stringent regulatory measures that need to be met before transgenic plants are allowed to enter the agricultural environment and the food chain. In the future, alternative approaches should bypass such regulatory hurdles providing legislatively acceptable routes toward the same goal. Advances in breeding techniques should allow naturally occurring alleles to be bred into commercial crop cultivars more easily. Cisgenic approaches, where endogenous gene sequences are used for genetic improvement may be seen as an advance over transgenics. Furthermore, the advent of targeted genome editing may prove to be of major importance for the commercialization of genetically designed plants (Voytas, 2013).

Elucidating and understanding the structures of normal, defective, or genetically engineered starch and glycogen clearly have everything to do with the biological function and commercial utility of the polysaccharides. Whilst significant progress has been made, better understanding and improved analytical methods to describe their structures would greatly facilitate progress, especially in the design of new starches for industrial purposes. In the genetic manipulation of starch structure, not only must we confront the imposing complexity of the

metabolic processes but also societal issues regarding the perceived value and acceptability of genetically altered natural products.

Introduction

Sulfated glycosaminoglycans (GAGs) are linear polysaccharides expressed ubiquitously in intracellular compartments, on the cell surface, and in the extracellular *milieu*. GAGs are ancient molecules that have withstood limited structural variation over evolution. For example, heparan sulfate (HS) is present in *Cnidaria* and all metazoans analyzed to date, with the exception of *Porifera*. *In vivo*, the sulfated GAGs, HS, heparin (HP), chondroitin sulfate (CS), dermatan sulfate (DS), and keratan sulfate (KS), are found covalently conjugated to specific core proteins as proteoglycans. Most cells express multiple proteoglycans. Studies of proteoglycans date back to the late nineteenth century when aggrecan (chondromucoid) was identified in cartilage. This was followed by the unexpected identification of HP (cephalin), a highly sulfated version of HS, as a potent anticoagulant in liver extracts (thus, the name heparin) in 1916 by a medical student who was trying to isolate a procoagulant molecule. HP was later determined to function as an anticoagulant by binding to antithrombin III and inducing a conformational change that facilitates its inhibitory action against procoagulant enzymes, such as thrombin and factor Xa. HS was initially recognized as a contaminant in the HP preparation, but was later distinguished from HP in the late 1940s by differences in the extent of sulfation and greater structural variability. For a long time, the biological functions of proteoglycans were largely speculative and, in fact, most proteoglycans were thought to be mainly specific to cartilage, functioning as lubricating, load-bearing cushions for variable, compressive forces in joints. We now know that proteoglycans also function as key modulators of many molecular and cellular interactions, which strongly influence diverse pathophysiological processes, such as development, immunity, infection, and cancer.

The type of sulfated GAGs attached to core proteins defines proteoglycans as HS proteoglycans (HSPGs), CS proteoglycans (CSPGs), or KS proteoglycans (KSPGs). In cases where the core protein carries several types of GAGs, the functionally dominant GAG chain defines the proteoglycan. For example, syndecan-1 contains both HS and CS chains, but is considered an HSPG based on this definition. GAGs are polysaccharides of repeating disaccharide units, which consist of uronic acid (UA) or galactose (Gal) and hexosamines. The basic disaccharide units of HS and HP are glucuronic acid (GlcA) or iduronic acid (IdoA) and *N*-acetylglucosamine (GlcNAc), whereas those of CS are GlcA and *N*-acetylgalactosamine (GalNAc), DS are GlcA or IdoA and GalNAc, and those of KS are Gal and GlcNAc. HS is differentially sulfated throughout the chain, whereas CS usually contains 1 or 2 sulfate groups per disaccharide. Sulfated GAGs are highly hydrophilic due to their negative charge, and are capable of holding large amounts of water molecules and have a large hydrodynamic volume. These properties allow several proteoglycans (e.g., aggrecan) to function as cushions for variable, compressive loads in joints. In contrast,

owing to the highly heterogeneous structure of HS chains, HSPGs can interact specifically with large number of proteins and regulate their biological activities in various cellular compartments.

Structure and Synthesis of Proteoglycans

Core Protein Structure

So far, more than 40 genetically distinct proteoglycan core proteins that bear one or several sulfated GAGs have been identified (Bernfield *et al.*, 1999; Filmus and Capurro, 2014; Scully *et al.*, 2012; Iozzo, 2005; Wight *et al.*, 2014; Iozzo and Schaefer, 2010). A partial list of proteoglycans and their sulfated GAGs is shown in Table 1. The core proteins have distinct structural designs with specific GAG attachment sites. The number of GAG chains on a core protein may vary from 1 to 100, and their length may vary from a few disaccharide units to hundreds. Furthermore, proteoglycans are expressed on different cells and cellular compartments, at different times and levels. In general, the core proteins direct the specific expression pattern of proteoglycans, although there are few exceptions (e.g., glypicans). In intracellular compartments, serglycin is mainly expressed in secretory vesicles of hematopoietic cells, but also found in vesicles of endothelial, endocrine, and tumor cells (Scully *et al.*, 2012). Serglycin contains a large number of Ser-Gly repeats (≥ 16), to which HP, CS, or DS chains are attached. Serglycin of connective tissue mast cells mostly contains HP, whereas that of mucosal tissue mast cell bears CS.

Cell surface proteoglycans include the syndecan and glypican families with four and six members in mammals, NG2, neuropilin, betaglycan, CD44, invariant chain, and thrombomodulin (Bernfield *et al.*, 1999; Couchman, 2010; Filmus and Capurro, 2014; Park *et al.*, 2000b). The latter four can exist with or without GAG chains and are therefore considered as part-time proteoglycans. Syndecans, NG2, betaglycan, CD44, invariant chain, and thrombomodulin are type I transmembrane core proteins whereas glypicans are linked to the cell surface by a glycosylphosphatidylinositol (GPI) anchor. Syndecan core proteins contain an extracellular domain extended in conformation due to a high Pro content. The sequence identity in glypicans could be as low as 25%, but their 3D structure is highly similar because the 14 highly conserved Cys residues form intramolecular disulfide bonds, resulting in a conserved globular structure. Two to four HS chains are attached distal to the plasma membrane on all syndecans and CS chains are also attached proximal to the plasma membrane on syndecan-1 and -3 (Kokenyesi and Bernfield, 1994), suggesting that HS interacts with extracellular proteins, whereas CS may interact with membrane proteins. In contrast, 2–5 HS chains are attached proximal to the plasma membrane in glypicans, suggesting that GAGs on glypicans primarily interact

with other cell surface molecules. Glypican-5 can also harbor CS chains. GAG attachment sites in NG2 (CS) and CD44 (HS/CS/DS) are located in the middle portion of the core protein, whereas those of thrombomodulin (CS) and betaglycan (HS/CS) are proximal to the cell surface. The transmembrane and short cytoplasmic domains of syndecans are highly conserved across species, and along with the specific GAG attachment sites, are the signature motifs of this HSPG family. The transmembrane domain contains a GxxxG dimerization motif that mediates both homotypic and heterotypic oligomerization of syndecans (Dews and Mackenzie, 2007). The syndecan cytoplasmic domain contains several signaling and scaffolding motifs, such as three highly conserved Tyr, one highly conserved Ser, and a C-terminal Glu-Phe-Tyr-Ala (EFYA) PDZ binding domain. The invariant Tyr residues have been shown to be important in the regulation of syndecan-1 shedding

(Hayashida *et al.*, 2008b), whereas the EFYA motif binds to the PDZ protein syntenin (Grootjans *et al.*, 1997) and regulates syndecan sorting to the basolateral surface (Maday *et al.*, 2008) and exosome biogenesis (Baietti *et al.*, 2012), among other functions. The NG2 cytoplasmic domain also contains a PDZ binding domain and several Thr residues that can be phosphorylated. The CD44 cytoplasmic domain contains an ezrin, radixin, moesin (ERM) motif that links cell surface CD44 to the actin cytoskeleton.

Expression of cell surface proteoglycans is polarized and developmentally regulated. For example, syndecan-1 is first detected at the 4-cell stage in mouse embryos (Sutherland *et al.*, 1991), indicating that its expression is zygotically activated. In adult tissues, syndecan-1 is mainly expressed on the surface of epithelial and plasma cells. In culture, syndecan-1 is expressed broadly on the cell surface in subconfluent epithelial

cells, but its expression becomes highly polarized to basolateral surfaces in confluent cells, consistent with its role in mediating cell–cell and cell–matrix adhesions (Figure 1). This expression pattern of syndecan-1 in polarized, confluent cells resembles that of syndecan-1 in simple epithelial sheets *in vivo*. Glypicans are mainly targeted to the apical surfaces, though they can sometimes be expressed on basolateral surfaces. Apical sorting of glypicans is inversely related to its HS content (Mertens *et al.*, 1996).

Perlecan, agrin, and collagen XVIII are secreted and are the major HSPGs of basement membranes (Iozzo, 2005). Perlecan is so named from its appearance as a string of pearls in rotary shadowing images. Perlecan is widely expressed in basement membranes of various tissues. Agrin is localized to the basement membrane of neuromuscular junctions. Perlecan harbors 3–4 HS chains, whereas agrin is predicted to have 4 HS chains. Perlecan also contains *N*- and *O*-linked branched sugars, which are thought to function in its secretion. The aggrecan family of secreted proteoglycans comprised of aggrecan,

versican, brevican, and neurocan contains an amino-terminal hyaluronan binding domain, a central region that harbors CS chains, and a C-terminal C-type lectin domain. Aggrecan is a large, aggregating CS and KS containing proteoglycan found mainly in cartilaginous tissues. About 100 CS and 30 KS chains typically decorate aggrecan. Versican is expressed in the pericellular environment of most tissues. Versican exists in at least 4 isoforms generated by alternative splicing of exons that code for 2 CS attachment domains in the core protein. The CS chains attached to versican vary in size and composition, depending on cell type and culture conditions (Wight *et al.*, 2014).

Biglycan, decorin, fibromodulin, lumican, epiphykan, keratan, and mimecan comprise the family of small leucine-rich proteoglycans (SLRPs) (Iozzo and Schaefer, 2010). SLRPs are secreted and primarily found in ECMs. The core proteins of SLRPs contain leucine-rich repeats, which occupy more than 70% of the core proteins. Similar to other proteoglycans, the core proteins of SLRPs have distinct structural

Figure 1 Expression of Syndecan-1 in Epithelial Cells. Normal murine mammary gland (NMG) epithelial cells at 10%, 30%, and 100% confluency were fixed in 4% paraformaldehyde, permeabilized, and immunostained with monoclonal rat anti-mouse syndecan-1 (281-2) and Alexa 594 (red) or mouse anti-HS (10E4) and Alexa 488 (green) antibodies and visualized. XZ images were generated by Image J from the Z stack of images taken through Zeiss Imager Z1 with apotome. Syndecan-1 and the HS epitope recognized by the 10E4 antibody are expressed mostly on the apical cell surface and in intracellular compartments in subconfluent cells, whereas syndecan-1 expression is polarized and predominantly on the basolateral cell surface in confluent cells.

designs with specific GAG attachment sites. For example, biglycan contains 2 CS or DS chains on a 38 kDa core protein. Decorin contains 1 CS or DS chain on a 36 kDa core protein. The CS containing decorin is found in developing bones, whereas the DS containing molecule is found in articular cartilage or tendon.

GAG Structure and Synthesis

GAGs are linear polysaccharides comprised of repeating disaccharide units that are defined by the composition and chemical linkage of the amino sugar and uronic acid monosaccharides in the disaccharide unit (Funderburgh, 2000; Esko and Selleck, 2002; Trowbridge and Gallo, 2002). The signature disaccharide repeat of a HS/HP is (GlcA β 1-4GlcNAc α 1-4) $_n$, CS is (GlcA β 1-3GalNAc β 1-4) $_n$, and DS is (GlcA/IdoA β 1-3GalNAc β 1-4) $_n$. CS and DS are distinguished from each other by the presence of GlcA and IdoA epimers. Except for KS, GAGs are attached to and polymerized on certain Ser residues of a Ser-Gly dipeptide sequence often repeated two or more times. KS chains are sulfated poly-*N*-acetyl lactosamines and classified based upon their core protein linkages. KS I is *N*-linked to specific Asn via high mannose type precursor oligosaccharide, KS II is *O*-linked to Ser or Thr via GalNAc, and KS III is *O*-linked to Ser or Thr via 2-*O*-mannose. Elongation of KS chains occurs through the enzymatic addition of Gal and GlcNAc, and sulfation of the polymer occurs at the 6-*O*-position of both sugar residues. The interaction of GAGs with proteins depends on their 3D structure, their sulfate substitution pattern, carboxyl groups, rotations around the glycosidic linkages, and the flexibility of the pyranose rings in the IdoA acid residues. The pyranose ring of the IdoA residue can assume both the 4C_1 chair and 4S_0 skew boat conformations and is flexible, which explains in part the extraordinary ability of IdoA containing GAGs, HP, HS, and DS, to bind to and regulate a wide range of proteins by facilitating the interaction of their anionic groups with cationic binding sites on proteins. Furthermore, HS chains are typically 50–200 disaccharide units in length, which equates to 40–160 nm in an extended, right-handed helical structure, suggesting that HS chains are a dominant feature of cell surfaces.

GAGs are attached to core proteins in a very specific and sequential manner by membrane-bound enzymes in the ER and multiple Golgi compartments (Funderburgh, 2000; Esko and Selleck, 2002; Trowbridge and Gallo, 2002). The biosynthesis of proteoglycans is a complex, nontemplate-driven process that requires many glycosyltransferases, an epimerase and sulfotransferases, which polymerize disaccharide units, epimerize GlcA to IdoA and sulfate nascent GAG chains. For example, HSPG synthesis is initiated by the formation of a tetrasaccharide linkage region (GlcA β 1-3Gal β 1-3Gal β 1-4Xyl β 1-*O*-Ser) on select Ser residues in the core protein. HS/HP synthesis is specified by the addition of an α 1,4-linked GlcNAc residue to the nonreducing end of the tetrasaccharide link attached to a Ser surrounded by a motif containing a hydrophobic amino acid adjacent to the Ser-Gly sequence and a cluster of acidic amino acids on the C-terminal side of Ser-Gly (Zhang *et al.*, 1995; Zhang and Esko, 1994). Synthesis of CS and DS uses an identical tetrasaccharide linkage region on

Ser residues in the Ser-Gly repeat, but the core protein motifs that specify CS/DS synthesis are not known.

HS is the most structurally complex GAG. Polymerization of the HS backbone proceeds by the addition of β 1,4-linked GlcA and α 1,4-linked GlcNAc units by glycosyltransferases of the exostosin family in alternating sequence to the nonreducing end of the growing polymer. Concomitant with HS chain elongation, several modifications occur through an epimerase and various sulfotransferases to generate a complex polysaccharide containing *N*-acetylated and *N*-sulfated glucosamine residues, GlcA and IdoA units, as well as *O*-sulfate groups in various positions. Various mutant CHO cell lines lacking specific HS biosynthetic enzymes have confirmed the specificity and sequential manner of HS biosynthesis, and the biological importance of HS and its modifications (Zhang *et al.*, 2006). Because the polymerization and modification reactions do not go to completion, the biosynthetic process generates an exceptionally diverse array of HS structure, both in length and extent of modification. Adding to the complexity is the fact that the composition of *N*- and *O*-sulfate groups in HS varies with cell type and tissue source. Thus, a mere HS decasaccharide can potentially assume over 10^6 distinct sequences, which is already in vast excess of the estimated gene products that the whole human genome can generate. This enormous structural diversity largely explains why and how HS binds to and regulates so many proteins.

Cellular Functions of Proteoglycans in Health and Disease

Proteoglycans have important developmental and post-developmental functions (Bernfield *et al.*, 1999; Iozzo and Sander-son, 2011; Wight *et al.*, 2014; Filmus and Capurro, 2014; Teng *et al.*, 2012; Perrimon and Bernfield, 2000). GAGs mediate the majority of ligand binding activities and endow proteoglycans the ability to interact with and regulate a multitude of protein ligands. The list includes growth factors, ECM components, cytokines, chemokines, antimicrobial peptides, coagulation factors, virulence factors, and many more (Xu and Esko, 2014; Schaefer and Iozzo, 2008; Filmus and Capurro, 2014; Bartlett and Park, 2010). Ligand binding by proteoglycans is primarily electrostatic, involving the anionic sulfate and carboxyl groups of GAGs and cationic ammonium, guanidinium, and imidazolium side chain functional groups of proteins.

Serglycin is critical in the maturation of mast cells, and regulates the storage and secretion of granule proteases, serotonin, and histamine in mast cells, platelets, neutrophils, and several other cells of hematopoietic origin (Scully *et al.*, 2012). These activities are mainly mediated by the HP chains since mice lacking *N*-deacetylase *N*-sulfotransferase-2, and hence HP chains, have abnormal mast cells with altered morphology and significantly reduced amounts of histamine and mast cell proteases (Forsberg *et al.*, 1999). HP is one of the oldest injectable drugs still in widespread clinical use (Wardrop and Keeling, 2008). HP has the highest negative charge density among the GAGs and also among any known biological molecule. HP functions as a potent anticoagulant by binding to and inducing a conformational change in antithrombin III, that facilitates the formation of tight, equimolar complexes of

antithrombin III with the serine proteases thrombin and factor Xa, resulting in efficient inhibition of these procoagulant enzymes. The minimum antithrombin III binding region in HP has been identified as a pentasaccharide sequence composed of 2 uronic acids and 3 glucosamine residues, with a 3-O-sulfated central glucosamine residue.

Cell surface proteoglycans, especially those harboring the structurally diverse HS chains, bind to a wide range of protein ligands and regulate cell–cell, cell–matrix, cell–growth factor, cell–morphogen, and cell–cytokine/chemokine interactions (Xu and Esko, 2014; Bernfield *et al.*, 1999; Couchman, 2010; Perrimon and Bernfield, 2000). Surface proteoglycans function as a receptor that translates the composition, organization, and stability of the extracellular environment into cellular activities. Surface proteoglycans can tether ligands and increase their local concentration at the cell surface, act as scaffolds and catalyze the encounter between ligands and their signaling receptors, increase the stability of ligands or receptors by protecting them from proteases, facilitate the oligomerization of ligands or receptors, or induce a conformational change of ligands or receptors (Xu and Esko, 2014; Bernfield *et al.*, 1999; Park *et al.*, 2000b). Cell surface proteoglycans function primarily as coreceptors for both soluble (e.g., growth factors) and insoluble ligands (e.g., ECM components) at the cell surface, though they can also serve as primary receptors for certain ligands, such as triglyceride-rich lipoproteins (Stanford *et al.*, 2009). Furthermore, cell surface HSPGs serve as endocytic receptors for several molecular cargo, such as cell penetrating peptides, polycation-nucleic acid complexes and morphogens, and modulate endocytic signaling (Christianson and Belting, 2014), whereas syndecan-1 can be transported to the nucleus where they have been shown to regulate transcription (Stewart and Sanderson, 2014).

The nature of the interaction of cell surface proteoglycans with growth factors has been the subject of intense study since the initial observation in 1991 that cell surface HSPGs are required for FGF-2 signaling (Yayon *et al.*, 1991; Rapraeger *et al.*, 1991). In the absence of cell surface HS, FGF-2 interacts poorly with its high affinity receptor (FGFR-1) and intracellular signaling is not activated. Cell surface HSPGs, such as syndecans, form a ternary complex with FGF-2 and FGFR-1, and this facilitates growth factor signaling. Subsequent studies have shown that HSPGs may regulate the oligomerization of both ligand and receptor (Schlessinger *et al.*, 1995), although some have also suggested that oligomerization is not essential (Pye and Gallagher, 1999). While the regulatory mechanism is not fully elucidated, it is clear that HSPGs bind specifically and tightly to FGF-2. In fact, crystal structures of complexes of FGF-2 with a HP-derived tetrasaccharide and hexasaccharide were the first reported for a protein-GAG oligosaccharide complex (Faham *et al.*, 1996).

In addition to FGF-2, cell surface HSPGs enhance the signaling of other growth factors and morphogens, such as EGF, VEGF, TGF β , HGF, sonic hedgehog (Hh), BMP, ephrin, and Wnt family proteins, among others (Bernfield *et al.*, 1999). Glypicans in particular are important regulators of growth factors and morphogens during development. Studies with *Drosophila* mutants have shown that glypicans control a diverse set of patterning events (Perrimon and Bernfield, 2000). Glypicans also function in axon guidance and formation of

excitatory synapses (Filmus and Capurro, 2014; Filmus *et al.*, 2008). Glypicans regulate the formation of Hh gradients, which is thought to be important in Simpson–Golabi–Behmel syndrome, a rare X-linked condition caused by a loss-of-function mutation of glypican-3 and characterized by pre- and postnatal overgrowth (Filmus and Capurro, 2014). Glypican-3 acts as an inhibitor of Hh signaling by competing with Patched for Hh binding. Interestingly, glypican-5 promotes Hh–Patched interaction by binding to both Hh and Patched through HS. How this is accomplished is not fully understood, but GPC5 is thought to function in this manner because HS chains of glypican-5 are more highly sulfated compared to those of glypican-3. In fact, glypican-5 is upregulated in rhabdomyosarcoma, and increased glypican-5 is thought to increase Hh signaling and promote cancer progression. Furthermore, a loss of function mutation in glypican-6 has been identified in patients with autosomal recessive omodyplasia, characterized by short-limbed short stature and craniofacial dysmorphism, consistent with reduced Hh activity in bones, indicating that glypicans are critical regulators of Hh signaling in many tissues. However, the activity of glypicans in the Wnt, Hh, and BMP signaling pathways is only partially dependent on the HS chains (Filmus *et al.*, 2008). Cell surface HSPGs also play important developmental roles in left-right development in the migrating mesoderm (Kramer *et al.*, 2002) and midline axon guidance (Inatani *et al.*, 2003). While differential phosphorylation of syndecan-2 by PKC γ in right ectodermal cells but not left cells is known to regulate left-right development, the HSPG that regulates midline axon guidance remains to be identified.

Cell surface HSPGs also control the onset and progression of various post-developmental diseases, including protein losing enteropathy (Bode *et al.*, 2008), Alzheimer's disease (Scholefield *et al.*, 2003), inflammatory disorders (Bartlett *et al.*, 2007), infection (Aquino *et al.*, 2010), and cancer (Iozzo and Sanderson, 2011). In protein losing enteropathy, syndecan-1 is required to maintain the integrity of intestinal epithelial barriers. While the underlying mechanism is not understood, HS chains of syndecan-1 are thought to bind to IFN γ and TNF α in an *N*-sulfate-dependent manner, and inhibit their detrimental effects on epithelial barrier integrity. In Alzheimer's disease, cell surface HSPGs bind to and inhibit Alzheimer's β -secretase (BACE-1) and the generation of amyloid β -peptide. Here, HS binds to and regulates BACE-1 in a 2-O- and 6-O-sulfate-dependent manner, but the identity of the cell surface HSPG responsible for this activity is not known. Cell surface HSPGs also regulate several key steps of leukocyte recruitment to sites of injury and infection. HSPGs bind to most chemokines in an HS-dependent manner, increase the local concentration of chemokines, and facilitate the formation of a chemokine gradient that guides the migration of inflammatory cells (Handel *et al.*, 2005). Solution NMR spectroscopy has clearly shown that GAGs play a major role in chemokine oligomerization and function (Pomin, 2014). Consistent with these observations, syndecan-1 has been shown to modulate leukocyte recruitment in various mouse models of inflammatory diseases (Teng *et al.*, 2012), including acute lung injury (Li *et al.*, 2002), allergic lung inflammation (Xu *et al.*, 2005) and systemic shock (Hayashida *et al.*, 2008a, 2009). In these inflammatory disorders, syndecan-1 promotes, or attenuates,

inflammation by regulating the compartmentalization, activity, or removal of various chemokines. In infectious disease, cell surface proteoglycans serve as attachment and invasion receptors for a wide variety of microbial pathogens, including viruses, bacteria, parasites, and fungi (Aquino *et al.*, 2010). For instance, *Neisseria gonorrhoeae*, one of the most common causes of bacterial sexually transmitted disease, binds to syndecan-1 and -4 via Opa proteins and stimulates a signaling pathway that involves phosphatidylcholine-specific phospholipase C, diacylglycerol, acidic sphingomyelinase, and ceramide, to invade host cells (Freissler *et al.*, 2000; Grassmé *et al.*, 1997). Herpes simplex virus has been shown to bind to an unusual *N*-unsubstituted and 3-*O*-sulfated glucosamine unit of cell surface HSPGs via gD protein to promote its infection (Shukla *et al.*, 1999). In cancer, the activity of cell surface HSPGs impinge on several key processes of tumorigenesis, such as cancer cell survival and apoptosis, angiogenesis, and metastasis (Iozzo and Sanderson, 2011; Teng *et al.*, 2012). Expression of syndecans and glypicans are highly altered in many cancers, suggesting that tumor cells regulate the expression of these cell surface HSPGs to promote their pathogenesis.

Interestingly many cell surface proteoglycans, including all members of the syndecan and glypican family, are released from the cell surface by highly regulated enzymatic mechanisms. The released proteoglycans are replete with their GAG chains and function as either paracrine or autocrine regulators of molecular interactions at the cell surface and in the extracellular milieu (Hayashida *et al.*, 2010; Teng *et al.*, 2012). Syndecans are shed from the cell surface by several metalloproteinases (Hayashida *et al.*, 2010; Teng *et al.*, 2012), whereas glypicans are mainly released by phospholipases, such as Notum (Traister *et al.*, 2008). Once released from the cell surface, proteoglycans show functions similar to or distinct from their immobilized counterparts. For example, several bacterial pathogens induce the release of syndecan-1 from the cell surface by activating an endogenous PTK- and MMP-dependent shedding mechanism (Park *et al.*, 2000a, 2004). Shed syndecan-1 has been shown to promote infection by inhibiting antimicrobial peptides and neutrophil-mediated bacterial killing mechanisms (Hayashida *et al.*, 2011; Park *et al.*, 2001).

Several secreted proteoglycans surround the cell and are ideally situated to regulate signaling by growth factors and other biological effectors. For instance, perlecan controls the pericellular concentration of various mitogens and morphogens, particularly growth factors of the FGF family (FGF-2, -7, and -10) (Aviezer *et al.*, 1994; Iozzo, 2005). Mice that lack perlecan have a complex series of developmental phenotypes, which is not confined to one tissue or organ system (Arikawa-Hirasawa *et al.*, 1999; Costell *et al.*, 1999). Mice that lack collagen XVIII have abnormalities in eye development and some effects on angiogenesis (Iozzo, 2005), whereas mice lacking agrin have defective neuromuscular junctions due to the inability to correctly cluster acetylcholine receptors on muscle fiber membranes (Gautam *et al.*, 1996). The negative charge of basement membrane proteoglycans also regulates the filtration properties of macromolecules in the vasculature, which is especially important in the kidney.

The aggrecan family of pericellular proteoglycans has important roles in cell-cell and cell-matrix adhesion, assembly

of ECM, and in providing the hyperosmotic properties necessary to counter compressive loads on tissues. Degradation of aggrecan by aggrecanases such as ADAMTS5 is a major cause of osteoarthritis (Stanton *et al.*, 2005), and mutations in genes for the aggrecan family core proteins and CS and DS biosynthetic enzymes can lead to chondrodysplasia and various disorders of connective tissues (Schwartz and Domowicz, 2002; Mizumoto *et al.*, 2013). Versican affects the adhesion and activation of chondrocytes and several leukocytes, including T cells and monocytes, and regulates the assembly of elastic fibers (Wight *et al.*, 2014).

The SLRP family of secreted proteoglycans regulates cellular responses to growth factors, immune responses, and assembly of collagen fibers in several tissues (Schaefer and Iozzo, 2008; Iozzo and Schaefer, 2010). Decorin has anti-proliferative effects on cancer cells via EGFR and c-Met (receptor for HGF) suppression. Lumican also inhibits tumor cell growth in soft agar by increasing the expression of the CDK inhibitor p21WAF1. However, in normal cells, decorin signaling through insulin-like growth factor receptor type I has anti-apoptotic and proliferative effects, favoring cellular growth. The SLRPs regulate collagen fibrillogenesis in the tendon and corneal stroma (Chakravarti *et al.*, 1998; Ezura *et al.*, 2000). Ablation of lumican in mice leads to disorganized collagen fibers and produces fragile skin and opaque corneas (Chakravarti *et al.*, 1998). Decorin, fibromodulin, and keratocan also bind to interstitial collagens and regulate collagen fiber assembly. Interestingly, lumican has been shown to bind to and present LPS to CD14, thereby activating TLR4 signaling in macrophages, whereas biglycan directly binds to and activates TLR2 and TLR4 and functions as a DAMP (danger-associated molecular pattern) (Iozzo and Schaefer, 2010).

Post-synthesis processing of GAGs also has a strong impact on cellular functions in health and disease. For example, membrane-bound HS sulfatases (SULF1 and SULF2), which remove 6-*O*-sulfate groups from HS, regulate FGF signaling and angiogenesis (Dhoot *et al.*, 2001; Wang *et al.*, 2004). Heparanase is an HS-specific endo- β -D-glucuronidase that plays multiple roles in growth factor signaling, cancer metastasis, diabetes, and atherosclerosis (Vlodavsky *et al.*, 2013). Heparanase is highly active in acidic conditions (pH 4–6.5), suggesting that it is primarily a lysosomal enzyme, but its expression and activity have been detected in cell membranes and in secreted forms. Proteoglycans are naturally degraded by an endocytic mechanism that involves proteolysis and endoglycosidic cleavage in intracellular vesicles, and degradation into monosaccharides and free sulfates by exoglycosidases and sulfatases in lysosomes. The inability to breakdown proteoglycans is characteristic of a group of genetic disorders called mucopolysaccharidoses, where deficiencies occur in one or more enzymes involved in the degradation of sulfated GAGs and hyaluronan (Lawrence *et al.*, 2014).

Research on proteoglycans and sulfated GAGs has come a long way since the discovery of aggrecan in cartilage. We now know that proteoglycans not only function as hyperosmotic cushions for variable, compressive forces in joints, but also as critical regulators of both developmental and post-developmental processes, involving cell-cell, cell-matrix, and receptor-ligand interactions. GAGs on proteoglycans bind to and regulate a wide variety of biological effectors in

intracellular, cell surface, and extracellular compartments, where they facilitate molecular interactions in various ways. However, much of their structure–function relationship remains to be elucidated as methodologies to analyze GAGs still lag behind those of protein biochemistry. Our understanding of how the synthesis and activities of proteoglycans are precisely regulated under normal and disease conditions also needs to be expanded to better understand their cell biology and to design and develop novel proteoglycan- and GAG-based therapies.

Primary Sources

'Hyaluronan Today,' accessible at the Glycoforum website, was initiated and sponsored by Seikagaku in 1997. Its purpose is to provide articles about the history and status of hyaluronan research in its many biological roles and functions. It presently contains 37 articles through to 2011 that provide overviews and references to the many hyaluronan 'branches' that are so nicely described in article 23, 'The Tree': Hyaluronan Research in the twentieth century, by Torvard Laurent (Laurent, 2002), one of the early pioneers in hyaluronan research. Hyaluronan is unique in many ways as described in this article (see Relevant Websites section).

Hyaluronan also has its own Society (International Society for Hyaluronan Sciences (ISHAS)) that was founded in 2004 by Endre Balazs, another early pioneer in hyaluronan research who focused on its roles and uses in medical applications. ISHAS now supports international hyaluronan conferences, and the program booklets from many previous conferences are accessible on the ISHAS website along with other current information about hyaluronan research. These sites are valuable sources of information and for contact information of many leaders in current hyaluronan research (see Relevant Websites section).

Another valuable source of information is the series of 5 hyaluronan books edited by Endre Balazs and published by the Matrix Biology Institute. This series includes interviews of many hyaluronan researchers conducted during 2000–2010 and chapters on the early history of research relevant to hyaluronan before the seminal work of Karl Meyer (see Relevant Websites section).

Introduction

In 1934, Karl Meyer and his assistant, John Palmer, described a procedure for isolating a novel glycosaminoglycan from the vitreous of bovine eyes (Meyer and Palmer, 1934; Hascall and Laurent, 1997). They showed that this substance contained a uronic acid and an aminosugar, but no sulfoesters. In their words: "we propose for convenience, the name 'hyaluronic acid,' from hyaloid (vitreous) + uronic acid." This marked the birth announcement for one of nature's most versatile and fascinating macromolecules. Today, this macromolecule is most frequently referred to as 'Hyaluronan,' reflecting the fact that it exists *in vivo* as a polyanion and not in a protonated form.

Structure and Cellular Metabolism

It took Karl Meyer's laboratory 20 years to determine the structure of the disaccharide (Weissman and Meyer, 1954; Figure 1(b)) that is the basic building block of the hyaluronan

glycosaminoglycan, typically synthesized with more than 10 000 repeat units for molecular masses $>5 \times 10^6$ Da (5 MDa; Figure 1(a)). Unlike the majority of other biomolecules, hyaluronan has no true molecular weight because in nature it does not have a unique size (number of sugars). All natural preparations of purified hyaluronan are very polydisperse, usually with sizes that span a 100-fold range. How do cells manage to do that? It requires only one enzyme, a hyaluronan synthase (HAS), and there are 3 such isozymes (HAS1-3) in vertebrate genomes (Weigel and DeAngelis, 2007; Spicer and MacDonald, 1998). In contrast to the other glycosaminoglycans (chondroitin/dermatan sulfates, heparin/heparan sulfate, and keratan sulfate), which are synthesized as proteoglycans on core proteins in the Golgi, hyaluronan is normally synthesized (not attached to a protein) at the plasma membrane using the cytosolic substrates, UDP-glucuronate and UDP-N-acetylglucosamine. The UDP-sugars are alternately

Figure 1 Disaccharide and domain structures of hyaluronan. (a) The ribbon structure of hyaluronan. The model shows how the hydrophilic structure of the large number of repeat disaccharides (GlcUA- β 1,3-GlcNAc- β 1,4) (b) of a hyaluronan macromolecule can occupy a large solvent domain that would hinder transport of large molecules while being permeable to small molecules. Modified from Hascall, V., Laurent, T., 1997. Hyaluronan: Structure and physical properties. Hyaluronan Today, article 1.

used as acceptors by being added onto the reducing end of a growing hyaluronan-UDP chain as the activating UDP is released, and the elongating chain is ratcheted through the enzyme itself within the plasma membrane into the extracellular space (Figure 2(a)). An animated cartoon (Weigel, 1998, Update 2005) illustrates how HAS might couple the addition of new sugars with the translocation of hyaluronan to the cell exterior, using only the energy provided by the activated sugar nucleotides. This novel intraprotein translocation mechanism, first proposed in 1999 (Tlapak-Simmons *et al.*, 1999), was later confirmed (Hubbard *et al.*, 2012). This product extrusion mechanism allows the final hyaluronan macromolecules to become very large as they are not constrained by synthesis in intracellular compartments. It is important to transport newly synthesized HAS enzymes to the plasma membrane before

they are activated. They are integrated into specific regions on the membrane that can form spikes when the enzyme is overexpressed and active, forming hedgehog-like cell structures (Kultti *et al.*, 2006; Figure 3). These regions are also involved in formation of exosomes that can package and transport proteins between cells and tissues (Rilla *et al.*, 2010).

Most cells are able to dynamically synthesize hyaluronan and form cell-associated glycocalyxes that include chondroitin sulfate proteoglycans (e.g., versican and aggrecan) bound to the hyaluronan (Figure 4). Some cells also have surface organelles that dynamically catabolize these glycocalyxes through cooperative action of a hyaluronan receptor, often CD44, a protease (e.g., an aggrecanase) and a hyaluronidase (Hyal) such as glycosylphosphatidylinositol (GPI)-anchored Hyal2 (Figure 4). The fragments are internalized into an

endosomal compartment ($t_{1/2} \sim 15$ min) that feeds them into lysosomes ($t_{1/2} \sim 3$ h) (Tammi *et al.*, 2001), and the receptor, protease, and hyaluronidase are cycled back to the cell surface.

This dynamic balance between hyaluronan synthesis and catabolism at the cellular level can regulate the cytosolic concentration of one of its substrates, UDP-GlcNAc, which is also a substrate for the intracellular O-GlcNAc transferase (OGT) (Figure 2(b)). This enzyme is critical for regulating many intracellular signaling pathways and cellular functions by adding GlcNAc to specific serine or threonine residues of target proteins, including kinases and key enzymes in metabolic pathways. If the cytosolic UDP-GlcNAc concentration is

Figure 4 Model for catabolism of hyaluronan glycoalyces. Cell surface proteins that bind hyaluronan (CD44), and cleave versican (aggrecanase) and hyaluronan (GPI-anchored hyaluronidase 2), internalize fragments of hyaluronan into an endosomal compartment. The proteins recycle to the cell surface, and the fragments are shuttled to lysosomes for complete degradation. Reproduced from Hascall, V., Wang, A., Tammi, M., *et al.*, 2014. The dynamic metabolism of hyaluronan regulates the cytosolic concentration of UDP-GlcNAc. *Matrix Biology* 35, 14–17.

elevated, as occurs in diabetic hyperglycemia, OGT adds GlcNAc to a large number of additional intracellular proteins, which alters and compromises cellular functions. A recent perspective (Hascall *et al.*, 2014) describes how OGT can regulate the activity of HAS2, the only synthase required for embryonic survival, by adding GlcNAc to a key serine, and how adenine monophosphate (AMP) kinase can stop HAS2 activity by phosphorylating a key threonine during metabolic stress (Figure 2(c)). This indicates that hyaluronan metabolism is likely a rheostat for maintaining stability of the cytosolic UDP-GlcNAc concentrations within an acceptable range.

Whole-Body Turnover of Hyaluronan

The pioneering work of Laurent and Fraser in the 1980s discovered that the synthesis and degradation of hyaluronan in mammals is extremely extensive and dynamic (Laurent and Fraser, 1992). Hyaluronan is continuously synthesized by most tissues, and a small fraction, as noted above, is deposited as a pericellular surface coat, while the majority is

incorporated into tissue biomatrices. This tissue hyaluronan is predominantly turned over systemically, rather than locally, via the lymphatics and vasculature through the action of receptor-mediated endocytosis in the lymph nodes and liver, and about one-third (~5 g) of total body hyaluronan is degraded and replaced every day (Figure 5). For example, the hyaluronan in the eye vitreous fluid is degraded in lymph nodes and liver. Very large (MDa) hyaluronan fragments (containing 'piggy-backed' bound proteins and chondroitin sulfate proteoglycans) are released from tissues undergoing continuous normal partial degradation of their biomatrices (i.e., turnover; Figure 5(a)). After entering the lymphatic circulation, approximately 85% of the hyaluronan is rapidly cleared by high-affinity endocytic isoreceptors in sinusoidal endothelial cells (SECs) of lymph nodes. The remaining hyaluronan that enters blood is then removed by the same receptors in the SECs of liver. Endocytosed hyaluronan is degraded intracellularly and the component sugars are reutilized for energy production or biosynthesis (Figure 5(b)).

Based on this process, first identified by Laurent, Fraser, and coworkers, the hyaluronan scavenger receptor was purified, cloned, and named the HA receptor for endocytosis (HARE) (Weigel and Yik, 2002). It was also named Stabilin-2 after the gene was found to be related to Stabilin1 (Politz *et al.*, 2002). Native tissues express two protein isoforms of different mass (e.g., 190 kDa and 315 kDa in human) that are not splice variants; the smaller variant is the C-terminal approximately 55% of the full-length protein. The smaller receptor is designated as HARE and the full-length receptor as Stab2. HARE/Stab2 is constitutively recycling receptors that are internalized via clathrin-coated pit-mediated endocytosis. Internalized ligands are delivered to lysosomes and receptors are recycled back to the cell surface (Figure 5(b)). HARE/Stab2 are highly expressed in SECs of lymph nodes, liver, spleen, and bone marrow, and also found in macrophages, corneal and lens epithelium, mesenchymal heart valve cells, ependymal brain ventricle cells, prismatic epithelial cells covering renal papillae, and oviduct. HARE/Stab2 are also the systemic clearance receptors for apoptotic cells and other ligands including heparin, chondroitin/dermatan sulfates, acetylated low-density lipoprotein (LDL), collagen N-terminal propeptides and advanced glycation end products. HARE mediates intracellular ERK and NF- κ B signaling in response to hyaluronan uptake (Pandey and Weigel, 2014).

Hyaluronan in Structural Matrices

Hyaluronan provides the backbone to anchor proteoglycans that have hyaluronan-binding domains as indicated for versican in cell glycocalyxes (Figure 4). Cartilages were the major tissues for early proteoglycan research that provided the data for the current aggregate model for aggrecan (Figure 6), the proteoglycan that provides the resistance of cartilage to compressive loading (Hardingham, 1998). Many matrix and cell receptors that interact with hyaluronan do so by having a highly conserved approximately 93 amino acid protein domain known as a link module. The G1 domain of aggrecan contains two link modules (Day, 2001) that bind to a decasaccharide length on the hyaluronan. This binding is

reversible until it is 'locked in' by the link protein that also has two link modules and a domain that interacts with the G1 domain. HASs evolved late in evolution, likely from a chitin synthase precursor, with subsequent evolution of the 23 genes encoding link modules in the human genome. The presence of this structural domain indicates that the protein has evolved to interact with hyaluronan as part of its biological functions. For example, the cell surface receptor CD44 has one link module that normally interacts with a hexasaccharide length on hyaluronan and is involved in several functions including roles in inflammations and cancer discussed below.

Hyaluronan in Fertilization and Embryogenesis

Cumulus-oocyte complex (COC) expansion and successful ovulation requires formation of an extensive hyaluronan matrix that must be penetrated by a sperm for fertilization via a membrane hyaluronidase in the sperm head (Salustri and Fulop, 1998). The structure of this matrix requires modification of the hyaluronan by a mechanism that is also prevalent in inflammation as discussed below. Prior to ovulation, the cumulus cells upregulate the levels of HAS2, TNF α -stimulated gene 6 (TSG6), and pentraxin 3. The follicle becomes permeable to serum, which allows entry of inter- α -inhibitor (I α I), an unusual proteoglycan with one chondroitin sulfate chain. The core protein of I α I is bikunin, a trypsin inhibitor, and the chondroitin sulfate chain contains 2 proteins (heavy chains (HCs)) bound by aspartate ester linkages to the 6-OH of GalNAc residues. TSG6 is an enzyme that migrates the HCs by trans-esterification from GalNAc on I α I to the 6-OH of GlcNAc on hyaluronan forming HC-hyaluronan chains (Figure 7). The presence of pentraxin 3 stabilizes the COC hyaluronan matrix (Ievoli *et al.*, 2011). Mice null in either TSG6, or bikunin, or pentraxin 3 do not form the matrix, have aberrant ovulation, and are female infertile.

Hyaluronan is required for several other embryonic processes. Has2-null mice are embryonic lethal due to failure to form heart valves, most likely arising from deficient ErbB2-ErbB3-Ras signaling and blockade of endothelial-mesenchymal transitions that occur during early heart development (Camenisch *et al.*, 2000, 2002). Hyaluronan is also critical for development of musculoskeletal and neural tissues, as well as formation of their tissue stem cell niches, due to its binding to signal-inducing cell surface receptors such as CD44 as well as its biophysical properties and interactions with other extracellular macromolecules (Vigetti *et al.*, 2010; Sherman and Feistel, 2008; Matsumoto *et al.*, 2009).

Hyaluronan in Inflammatory Pathologies

The HC-hyaluronan structure was first identified in the 1960s in analyses of hyaluronan isolated from synovial fluids of patients with rheumatoid arthritis (Sandson *et al.*, 1965). Immunodiffusion assays showed that hyaluronidase treatment released a protein that gave precipitates with antiserum against I α I, which was thought to be a single protein at that time. The HC protein was not present on hyaluronan from synovial fluids from individuals who did not have rheumatoid arthritis. This mechanism was rediscovered in the 1990s as a

Figure 5 Systemic clearance of hyaluronan by HARE/Stab2 in lymph nodes and liver. (a) The schematic overview, based on the discoveries of Laurent and Fraser (1992), depicts the dynamic process by which mammals synthesize and degrade (i.e., turnover) about one-third of total body hyaluronan every day (~ 5 g in humans). The mass range of hyaluronan during this process is indicated (bottom) by red curved lines. All tissue biomatrices (upper right) normally undergo slow and continuous partial degradation that releases large fragments of hyaluronan (≥ 1 mDa) from native tissue hyaluronan (up to 10 MDa); the hyaluronan fragments also contain bound proteoglycans and other proteins (e.g., link protein and hyaladherins). As they flow into lymph nodes (lower right), most of these fragments are internalized and degraded by SECs. The hyaluronan that escapes clearance ($\sim 15\%$) and enters the blood (bottom) is smaller (<1 MDa) and is then internalized by the same HARE/Stab2 receptors in SECs of the liver (left). At normal steady-state in healthy people, the hyaluronan size in blood is approximately 100–150 kDa and the concentration is $<40 \mu\text{g l}^{-1}$. (b) HARE/Stab2 clearance receptors (blue) on the surface of SECs are continuously targeted to clathrin (gray) coated pits (#1), whether they are bound to hyaluronan (red coils) or not; they are constitutively endocytosed and recycled. After coated pit-mediated endocytosis (#3) and clathrin uncoating (#4), endosomes containing receptor-ligand complexes are delivered (#5) to a compartment for uncoupling receptor-ligand (CURL), in which dissociation occurs facilitated by low pH, to produce free hyaluronan that is delivered to lysosomes for degradation (#6) and free receptors, which are directed to recycling endosomes (#7). These vesicles return HARE/Stab2 to the plasma membrane (#8) where they begin another cycle of internalization. Reproduced from Weigel, P., Yik, J., 2002. Glycans as endocytosis signals: The cases of the asialoglycoprotein and hyaluronan/chondroitin sulfate receptors. *Biochimica et Biophysica Acta* 1572, 341–363.

'serum-derived hyaluronan-associated protein' (SHAP) that modified hyaluronan in fibroblast cultures, and was shown to be the heavy chains from IαI (Kimata and Zhuo, 2001).

Figure 6 Model for aggregates of the proteoglycan aggrecan. The G1 domain of aggrecan (pink globe) and the associated link protein (white globe) are anchored on the central hyaluronan strand. Aggrecan contains two additional globular domains (G2, green globe and G3, purple globe) and has approximately 100 chondroitin sulfate chains (blue lines) and approximately 50 keratan sulfate chains (red lines).

In binding assays, lymphocytes bound to HC-hyaluronan coated surfaces >50-fold more than to equivalent concentrations of hyaluronan coated surfaces, indicating that this covalent protein modification of hyaluronan matrices has a significant role in inflammatory pathologies.

Experiments during this time also showed that colon smooth muscle cells treated with a virus or poly I:C, a viral mimetic, synthesized extensive structures referred to as hyaluronan cables. Monocytes bound to these structures at 4 °C and rapidly degraded them at 37 °C with capping of CD44 over phagocytosed hyaluronan fragments (Strong and de la Motte, 1999; Wang *et al.*, 2011) (Figure 8). The importance of CD44 for this process was shown in CD44-null mice treated with bleomycin, a noxious agent that induces inflammation in the lung (Teder *et al.*, 2002). Hyaluronan matrices increased significantly, and monocytes/macrophages extravasated into the inflamed areas. In the wild type mice, the hyaluronan matrix was removed and the inflammatory cells disappeared with restoration of normal lung function. In contrast, the monocytes continued to enter the lung connective tissue in the CD44-null mice but were unable to remove the hyaluronan matrix, and the mice died.

Almost all inflammatory pathologies, from wound healing to atherosclerosis to inflammatory bowel disease, involve early synthesis of the monocyte-adhesive matrix by the stressed cells (Strong and de la Motte, 1999; Wight, 1999). This matrix defines the location of the pathology and initiates the

Figure 7 Model for heavy chain (HC) transfer from inter- α -trypsin inhibitor (I α I) to hyaluronan by TNF α -stimulated gene 6 (TSG6). TSG6 (orange triangle) transfers HCs (green) from the chondroitin sulfate chain of I α I to hyaluronan in many inflammations and during hyaluronan matrix formation in cumulus cell-oocyte complex expansion and ovulation.

Figure 8 Hyaluronan cable structure and phagocytosis. (a) Monocytes (U937 cells) bind to a hyaluronan cable structure at 4 °C on colon smooth muscle cells treated with a viral mimetic poly I:C. Hyaluronan is stained green and CD44 is red. The monocytes do not interact with the hyaluronan coat on the smooth muscle cells in the background. (b) Monocytes phagocytose the hyaluronan matrix when cells as in (a) are warmed to 37 °C for 15 min. The inset shows the capped CD44 receptors with internalized hyaluronan. (c) A micrograph of an asthmatic lung biopsy with CD44-capped monocytes embedded in the pathological hyaluronan matrix. Modified from Wang, A., de la Motte, C., Lauer, M., Hascall, V., 2011. Hyaluronan matrices in pathobiological processes. *FEBS Journal* 278, 1412–1418.

sequence of events that follows – the influx of neutrophils (wound healing) or eosinophils (asthma) followed by the monocytes/macrophages, the removal of the hyaluronan matrix, and subsequent reconstruction. This process can restore the matrix to give normal tissue or fibrotic tissue, as in scar formation after wound healing.

Hyaluronan in Diabetic Pathologies

An experiment with a surprising result showed that vascular cells dividing in the medium commonly used for their culture induced hyaluronan accumulation intracellularly (Evanko and Wight, 2001). This presented a conundrum described in a subsequent review (Hascall *et al.*, 2004). However, the medium used was hyperglycemic, approximately 5x normal. Subsequent experiments with mesangial cells (Ren *et al.*, 2009) and bone marrow stromal (stem) cells (Wang *et al.*, 2014) showed that cells dividing in medium with more than 3x normal glucose levels activate HASs in intracellular compartments, including endoplasmic reticulum and transport vesicles (Figure 2(d)). This induced an autophagy response and a cyclin D3-mediated extrusion of hyaluronan to form a monocyte-adhesive hyaluronan matrix at the end of cell division. This mechanism compromised mesangial glomerular function in streptozotocin diabetic rats with development of proteinuria and nephropathy. The hyperglycemic bone marrow stromal cells differentiated into pathological adipocytes *in vitro* and *in vivo* with extensive formation of the monocyte-adhesive hyaluronan matrix that recruited large numbers of inflammatory cells *in vivo* with subsequent loss of mineral in trabecular bone. The diversion of stem cells that divide in hyperglycemia to this pathological adipogenesis pathway is highly likely to be a major mechanism underlying the ongoing diabetic epidemic with obesity and elevated risks of inflammatory pathologies.

Hyaluronan in Cancer

Hyaluronan deposition around tumor cells and in the tumor stroma correlates with progression of many types of human cancer (Tammi *et al.*, 2008). Correspondingly, a large amount of experimental data supports a pro-tumorigenic role for hyaluronan (Toole, 2009). However, the role of hyaluronan is complex, since experimental over-expression of hyaluronan in tumor cells can be either pro- or anti-tumorigenic, depending on the context. One contributing factor is hyaluronan turnover (Simpson and Lokeshwar, 2008), but other factors, such as molecular size of hyaluronan, are also likely to be important (Tian *et al.*, 2013). Irrespective of these complexities, it is clear that hyaluronan has a critical role in cancer. In addition to expected structural contributions to the tumor stroma, hyaluronan interacts with cell surface receptors that collaborate in driving intracellular signaling pathways and transporter activities that promote tumor progression.

Pericellular hyaluronan interacts with several cell surface receptors, including CD44, RHAMM, LYVE-1, HARE/stabilin-2, and Toll-like receptors-2 and 4 (Day, 2001). The major hyaluronan receptor implicated in cancer is CD44. However, RHAMM and CD44 can exhibit both cooperative and

interchangeable signaling functions. For example, interactions at the plasma membrane between RHAMM and CD44 have been shown to activate CD44 signaling through ERK1/2 and promote cancer cell motility (Maxwell *et al.*, 2008). In some cases, such as animal models of autoimmune diseases, RHAMM can compensate for CD44, a very important consideration when interpreting experiments in CD44-null mice (Naor *et al.*, 2007). LYVE-1 has been shown to have a similar role to CD44 in virally infected lymphoma cells (Qin *et al.*, 2011). HARE/Stab2 can also serve as homing receptors for hyaluronan-mediated tumor cell metastasis, since they are most prominently expressed in liver, lymph nodes, and bone marrow, all of which tissues are frequently colonized by metastatic tumor cells of epithelial origin bearing surface hyaluronan coats. Blocking hyaluronan binding to HARE in mice implanted with human prostate tumor cells almost completely prevents metastasis to lymph nodes (Simpson *et al.*, 2012).

CD44 is a single chain, single-pass, transmembrane glycoprotein that is very widely expressed in physiological and pathological systems. CD44 was first characterized through the confluence of several areas of investigation, including hyaluronan–cell interactions, lymphocyte homing, and cell adhesion (Toole, 1990; Knudson and Knudson, 2005). Although CD44 arises from a single gene, different transcripts are formed by alternative splicing. In several types of cancer cells, binding of hyaluronan to CD44 results in direct or indirect interaction of CD44 with signaling receptors, such as ErbB2, EGFR, and TGF- β receptor type I, and influences the activity of these receptors (Figure 9). It can also lead to interaction with and altered activity of non-receptor kinases of the Src family or Ras family GTPases (Bourguignon, 2008). Thus, hyaluronan–CD44 binding influences the activity of a variety of downstream signaling pathways, especially the MAP kinase and PI3 kinase/Akt pathways. In addition, binding of hyaluronan to CD44 stimulates multidrug and metabolic transporters that are important in malignancy and therapy resistance, and the cytosolic domain of CD44 interacts with the actin cytoskeleton via ankyrin or members of the ezrin-radixin-moesin family, consequently promoting tumor cell proliferation, survival, motility, invasiveness, and chemoresistance (Toole, 2009; Bourguignon, 2008; Ponta *et al.*, 2003). CD44 is often localized at least in part to lipid microdomains with the properties of lipid rafts, and associates indirectly or directly therein with signaling proteins and transporters (Toole, 2009). Figure 9 emphasizes cell autonomous activities influenced by hyaluronan produced by tumor cells. Hyaluronan produced by stromal cells may have overlapping or different activities, and interactions between the two compartments very likely contribute further to the malignant properties of tumors (Knudson *et al.*, 1984; Itano and Kimata, 2008). Given the large number of pathways affected by CD44, it is likely that indirect and direct interactions with a wide variety of effectors within such domains can be induced and/or stabilized by multivalent interactions of hyaluronan with CD44, which provides a likely mechanism whereby hyaluronan–CD44 interactions have such broad effects (Figure 9). Importantly, antagonists of these interactions that result in attenuation of pro-tumorigenic or therapy-resistant activities provide promising new therapeutic approaches in cancer patients (Toole, 2009; Misra *et al.*, 2009).

Figure 9 Regulation of signaling cascades in cancer cells by hyaluronan-CD44 interactions. Hyaluronan synthases produce and extrude hyaluronan, which interacts multivalently with CD44 to induce and/or stabilize signaling domains within the plasma membrane. These signaling domains contain various signaling receptors and non-receptor kinases that drive cell proliferation and survival pathways, as well as various transporters that participate in drug resistance and altered metabolic properties in cancer cells. Moreover, hyaluronan-CD44 interactions induce cytoskeletal changes that promote cell motility and invasion. Proteoglycans and associated factors attached to pericellular hyaluronan may also influence these activities. Reproduced from Toole, B.P., 2009. Hyaluronan-CD44 interactions in cancer: Paradoxes and possibilities. *Clinical Cancer Research* 15, 7462–7468.

Conclusions

This article provides an overview of the dynamic biochemistry and biology of hyaluronan. Research on this intriguing macromolecule continues at a rapid pace and is likely to discover yet more of its intriguing functions. The article has not addressed its expanding use in clinical and therapeutic treatments, regenerative medicine or as a material to form matrices that can incorporate other molecules or cells. These important areas are expanding steadily and would be appropriate for a future hyaluronan chapter.

Glossary

Acetyl-CoA/CoA ratio An index of the acetylation potential of the cell. Set at different ratios in the cytosol and mitochondrial matrix space and varies with nutritional state. It is usually determined in the mitochondrial matrix space by the relative rates of fatty acid oxidation and citric acid cycle.

Allosteric control A control mechanism by which a small molecule affects one or more of the kinetic parameters of an enzyme by binding to a site on the protein other than the active site. Positive allosteric effectors increase enzyme activity. Negative allosteric effectors decrease enzyme activity.

Cellular compartments Spaces enclosed by biological membranes create cellular compartments. These include the cytosol which is enclosed by the plasma membrane and the mitochondrial matrix space which is enclosed by the mitochondrial inner membrane. These compartments serve as a way to separate metabolic pathways that involve common intermediates, for example, fatty acid oxidation in the mitochondrial matrix space and fatty acid synthesis in the cytosol.

Covalent modification A control mechanism by which covalent modification of the side chain of an amino acid residue of an enzyme affects the kinetic parameters of that enzyme. Depending upon the enzyme and the modification, the effect can have a positive or negative effect on enzyme activity. Common covalent modifications include phosphorylation, acetylation, acylation, succinylation, and methylation.

Energy charge An index of the energy status of cells. It is defined as $([ATP] + \frac{1}{2} [ADP]) / ([ATP] + [ADP] + [AMP])$. Energy charge values range from 0 (all AMP) to 1.0 (all ATP). Cells maintain the energy charge within the narrow range of 0.8 to 0.95 by modifying rates of ATP producing and ATP utilizing reactions.

Isozymes or isoenzymes Enzymes that are different gene products but catalyze the same reaction, for example, HK 1, 2, 3, and 4 all catalyze the reaction of glucose + ATP yields G6P + ADP. Isozymes invariably differ with respect to their kinetic characteristics (K_m , V_{max}) and regulatory mechanisms (sensitivity to allosteric effectors, whether subject to covalent modification, whether regulated by gene transcription).

Malate/aspartate shuttle Cyclic pathway that transports reducing equivalents in the form of NADH from the cytosol into the mitochondrial matrix space (mitosol). The sum reaction for the cycle is $NADH_{cytosol} + NAD^+_{mitosol}$ yields $NAD^+_{cytosol} + NADH_{mitosol}$.

NAD^+ /NADH ratio An index of the redox state of the cell. Set at different ratios in the cytosol and mitochondrial matrix space and varies with the nutritional state. It is usually determined in the mitochondrial matrix space by the relative rates of fatty acid oxidation and the electron transport chain.

Oxidative phosphorylation The process by which the energy requiring reaction of ATP synthesis from ADP and Pi is coupled to the energy producing pathway of electron transport.

Phosphorylation potential An index of the energy status of cells. It is calculated from the equation $[ATP]/[ADP][Pi]$ which derives from the free energy change for ATP hydrolysis. Accurate determination requires estimation of the free concentrations of the nucleotides and inorganic phosphate. Cells maintain very high phosphorylation potentials to drive high energy requiring anabolic processes.

Tricarboxylic acid (TCA) cycle, Krebs cycle, citric acid cycle Cycle that oxidizes acetyl-CoA to CO_2 with the production of NADH and FADH₂ which in turn are oxidized by the electron transport chain with the production of ATP by oxidative phosphorylation. It is named after Hans Krebs who discovered the citric acid cycle.

Introduction

Metabolic regulation is a term used to describe the process by which metabolic pathways (both the anabolic/biosynthetic and catabolic/degradative pathways) are regulated in mammals. Living organisms need to generate energy continuously to maintain cellular processes and functions. The ability to oxidize available substrates (termed as fuels) to maintain energy needs (energy homeostasis) is central to survival of an organism. In mammals a near constant level of blood glucose (glucose homeostasis) is maintained to supply this fuel for energy production by the brain and other tissues. Hence, the maintenance of energy homeostasis and glucose homeostasis is critical for the function and survival of mammals during the fed as well as the fasting states (due to intermittent consumption of dietary fuels). Insulin and glucagon produce opposite effects upon metabolic processes. Caloric homeostasis in the fed and the fasted states depends upon a continuous monitoring and adjustment of the blood concentrations of insulin and glucagon. A change in the flux in a metabolic pathway is achieved by modulating the activity of one or more key enzymes (regulatory enzymes) which are subject to a variety of mechanisms to control their activities. Thus, by modulating the flux through various metabolic pathways to meet the metabolic needs of different organs, the body is able to maintain both its energy homeostasis and glucose homeostasis by utilizing the available fuels either from the dietary sources or from the internal tissue deposits.

The purpose of this article is to provide a summary of well-established principles of metabolic regulation in cells and tissues of animals. Rather than an exhaustive description of what is known about the regulation of a particular enzyme or a metabolic pathway, we discuss metabolic regulation in the context of physiological conditions that will be of interest to most readers. In our experience as investigators in this field as well as teachers of medical biochemistry, we have found that the remarkable ways in which the liver is able to change from an organ that synthesizes fuels for storage in the fed state to an organ that provides fuels for the rest of the body is a good way to gain an appreciation of the different mechanisms by which metabolic pathways are regulated (Figure 1).

Mechanisms for Regulation of Key Enzymes

Before we discuss the alterations in the pathways involved in glucose metabolism in the liver during the fed and fasted states, the mechanisms involved in controlling the rates of key regulatory enzymes need to be discussed. Although a change in the overall flux in a given pathway determines the contribution of that pathway in the metabolism in tissues, the control of this change in the flux is achieved by regulating key enzymes in the given pathway (usually more than one). This control of key enzymes can be achieved by five different mechanisms.

Substrates (Fuel) Availability

In the fed state, markedly increased availability of the circulating fuels (glucose, amino acids, and triacylglycerols) along

Figure 1 The pathways involved in glucose metabolism in the liver during the fed and fasted states. The major pathways depicted here are: glycolysis, glycogen synthesis and degradation, the tricarboxylic acid cycle, lipogenesis, and gluconeogenesis. These pathways are abbreviated to highlight the key regulatory enzymes. The key enzymes and the transporter in the biosynthetic pathways in the liver during the fed state are shown in green color and the key enzymes in the degradative pathways operating in the fasted state are in red color. Enzyme abbreviation used are: HK, hexokinase; GK, glucokinase; GLUT2, glucose transporter 2; Gly syn, glycogen synthase; Gly phos, glycogen phosphorylase; PFK-1, phosphofructokinase-1; PFK-2, phosphofructokinase-2; F-1,6-bisPase, fructose-1,6-bisphosphatase; PK, pyruvate kinase; PDC, pyruvate dehydrogenase complex; PC, pyruvate carboxylase; ACL, ATP-citrate lyase; ACC, acetyl-CoA carboxylase; FAS, fatty acid synthase. Abbreviations used for intermediates are commonly used in the metabolic pathways.

with the increased levels of circulating insulin set the stage for anabolic metabolism in all tissues. In the fasted state, a change in the levels of circulating hormones favoring the action of glucagon signals for mobilization (as glucose, free fatty acid, glycerol, lactate, pyruvate, and amino acids) of the stored fuels in the forms of glycogen in the liver, triacylglycerols (TAGs) in adipose tissues and proteins in skeletal muscle. Several enzymes and transporters have high K_m s for their substrates and hence they operate mainly when the concentration of the required substrates is increased (e.g., hepatic glucokinase, an isoenzyme of hexokinase, when the portal level of glucose is markedly increased during absorption after a mixed meal).

Allosteric Modulation

A change in enzyme activity by an allosteric mechanism brought about by a conformational change in the enzyme by binding of a small molecule in the site other than the active site. This type of enzyme is generally a dimer or higher order of organization. The change in activity (activation or inhibition) occurs as rapidly as the level of an allosteric compound changes in the cell and hence is referred to as short-term control.

Covalent Modification (or Posttranslational Modification)

A covalent modification refers to attachment/removal of a group (such as phosphoryl, acetyl, etc.) to/from a specific amino acid residue on an enzyme/protein. This change results in either activation or inactivation of enzyme activity. A change in enzyme activity by a covalent modification (e.g., phosphorylation of a serine residue on an enzyme by a post-translational modification) is rapid (short-term control) with often all-or-none activity of a modified enzyme molecule. This is probably the most effective way to regulate enzyme activity.

Interconversion of a key regulatory enzyme between its two forms (active and inactive) by covalent modification imparting different kinetic and allosteric properties often provides not only a unique control for its regulation but also by its interactions with a group of key enzymes involved in the biosynthetic and degradative pathways involved in a given metabolic process (e.g., protein-protein interactions among phosphorylase kinase, glycogen phosphorylase, and glycogen synthase in glycogen metabolism).

Inhibitory Protein (Regulatory Protein) Interaction

Binding of an inhibitory protein (aka regulatory protein) to an enzyme interferes with enzyme action. For example, binding of glucokinase inhibitory protein to glucokinase inhibits its activity. Similarly, binding of a specific inhibitory protein (aka regulatory protein) to protein kinase A (catalytic protein) inactivates protein kinase A. When cAMP binds to the inhibitory protein, it dissociates from protein kinase A making the latter an active enzyme.

Transcriptional and Degradational Control

A change (either increase or decrease) in the transcriptional rate of a gene by its transcriptional induction or repression eventually results in an alteration in the level of enzyme content (actual number of enzyme molecules) per cell. This is a relatively slow response requiring hours if not days for a significant response (and hence referred to as a long-term control). This control mechanism modulates the metabolic capacities of tissues over a longer time period in days and weeks under a given dietary condition. With some enzymes, levels are also regulated by degradation of the steady state amount of the protein.

Metabolism in the Fed State

An average American diet for adults provides approximately 2500 kcal day⁻¹ as percentage of calories from three major components: 40–50% from carbohydrates, 35–40% from fats, and 12–15% from proteins. This level of calories per day is commonly ingested in the form of three meals supplemented with a couple of small snacks. Hence each meal (initiating the fed state) provides a larger excess of calories than what can be utilized immediately for the cellular needs. The fed state refers to the time period following the consumption of a meal in which the glucose, amino acids, and fatty acids derived from the carbohydrate, protein, and fat in the diet are being absorbed from the intestinal tract and distributed in the body by the blood. The excess of the consumed calorie as fuels need to be converted into storage forms such as glycogen in liver (**Figure 1**) and skeletal muscle and TAGs in adipose tissues. Absorptive state initiated after ingestion of a mixed meal causes transient increases in plasma glucose, amino acids, and TAGs (as chylomicrons and very low density lipoproteins called VLDL). Increased levels of glucose and amino acids in the plasma stimulate insulin secretion and diminish glucagon secretion by the endocrine pancreas, resulting in an increased molar ratio of insulin:glucagon in the plasma in the absorptive state. This change in the hormonal levels sets the direction of anabolic metabolism in all tissues and lasts for about 2–4 h depending upon the size and composition of a meal.

Action of Insulin

The binding of insulin to its receptor (a protein tyrosine kinase) on the plasma membrane results in the activation of a series of protein kinases that increase the enzymatic capacity for glucose uptake, glycogen synthesis, and fat synthesis (**Figure 2**). Glucose uptake in skeletal muscle and adipose tissue is increased by stimulating the translocation of glucose transporter 4 (GLUT4) loaded intracellular vesicles to the plasma membrane (**Figure 2**). The synthesis of glycogen is increased in liver and skeletal muscle by activation of glycogen-bound phosphatases (such as protein phosphatase-1, PP-1) that activate glycogen synthase by dephosphorylation (**Figure 2**). The synthesis of fat is increased in liver and adipose tissue by promoting gene transcription and subsequent synthesis of lipogenic enzymes that include acetyl-CoA carboxylase (ACC) (**Figure 1**), fatty acid synthase (FAS), malic enzyme (ME), and fatty acid desaturases (**Figure 1**). Furthermore, there is increased VLDL synthesis and secretion by the liver (**Figure 1**), and increased synthesis of TAGs in adipose tissues as well as deposition of TAG derived from chylomicrons and VLDL in adipose tissue to store excess calories derived from dietary carbohydrates and fats. Also, protein synthesis is enhanced in all tissues especially in the skeletal muscle. The major tissues of interest in this metabolic interplay are liver, skeletal muscle, adipose tissues, and the brain. To illustrate the major regulatory mechanisms, we will discuss the metabolism of glucose by the liver during the fed state.

Glucose Metabolism in the Liver (in the Fed State)

Glucose transport and its phosphorylation

It is no wonder that the liver is considered a processing plant for handling of excess fuels for storage in the fed state and

Figure 2 Insulin promotes glucose uptake, glycogen synthesis, and fatty acid synthesis in tissues. The insulin signaling pathway involves activation of PI3K (phosphoinositide 3-kinase), Akt which is also known as PKB (protein kinase B), mTORC1 (mammalian target of rapamycin complex 1), and S6K (S6 ribosomal protein kinase). Akt/PKB promotes activation of glycogen-associated protein phosphatases (probably both PP1 and PP2A) which activate Gly syn (glycogen synthase) and inactivate Phos kinase (phosphorylase kinase) and Gly Phos (glycogen phosphorylase) by dephosphorylation in the liver and skeletal muscle. Akt/PKB also promotes the translocation of vesicles with membrane-bound GLUT4 (glucose transporter 4) from cytosol to the plasma membrane in skeletal muscle and adipose tissues where they fuse and thereby increase the capacity for glucose uptake from the blood. By a mechanism that is a subject of current research, S6K activates proteolytic processing of SREBP-1c (sterol response element binding protein 1c) to produce an active SREBP-1c peptide fragment that binds to the promoter for ACC (acetyl-CoA carboxylase) and promotes ACC transcription. Increased ACC expression along with increased expression of several other lipogenic enzymes increases the rate of fatty acid synthesis in the liver and adipose tissue.

manufacturing/supplying the fuels to the rest of the body during the fasting state. Liver possesses two unique glucose sensors, namely glucose transporter 2 (GLUT2) and glucokinase (both with high K_m for glucose) (Agius, 2008). Hence the transport of glucose in hepatocytes is increased via GLUT2 and its phosphorylation to glucose-6-phosphate is enhanced by glucokinase (in addition to hexokinase with a low K_m , <0.1 mM, for glucose present in hepatocytes). Hence glucokinase activity increases rapidly as glucose concentration in the liver rises (via blood supply by the portal vein) during the absorptive state. Since glucokinase is not inhibited by its reaction product (in contrast to hexokinase), it allows rapid phosphorylation of glucose to glucose-6-phosphate for its metabolism via different pathways. Interestingly, activity of glucokinase is inhibited by its interaction with glucokinase regulatory protein in the presence of fructose-6-phosphate (which is in equilibrium with glucose-6-phosphate by the action of phosphoglucose isomerase) and this inhibition is overcome by fructose-1-phosphate formed from fructose metabolism (from dietary source as sucrose) in the liver (not shown in figure).

Regulation of glycogen synthesis

Glucose-6-phosphate is readily utilized for the synthesis and storage of glycogen and its metabolism is enhanced to pyruvate via the glycolytic pathway due to the action of several regulatory enzymes under the control of insulin-mediated actions. Acetyl-CoA generated from pyruvate via the action of the pyruvate dehydrogenase complex (PDC) is largely diverted for the synthesis of long-chain fatty acids and cholesterol for the formation of VLDL, and is also oxidized via the tricarboxylic acid (TCA) cycle to generate ATP to support the biosynthetic processes, as indicated. These biosynthetic pathways are enhanced by activation of several key regulatory enzymes by their dephosphorylation (covalent modification) (Figure 2) as well as the changes in the levels of allosteric modulators (Table 1). Dephosphorylation of these regulatory enzymes is achieved by the activation of phosphoprotein phosphatase-1 (PP-1) mediated by the action of insulin (Figure 2) (Roach *et al.*, 2012).

Glycogen synthase is the regulatory enzyme in the pathway of glycogen synthesis and is subject to regulation by three mechanisms listed above. The phosphorylated form of glycogen synthase (also referred to as 'D' form for Dependent form;

Table 1 Regulation of several key enzymes in glucose metabolism by their phosphorylation status and allosteric modifiers in the liver

Enzyme	Compounds (+ activator/– inhibitor)	Active enzyme (phosphorylation status)
Glycogen synthase	+ Glucose-6-P + Glucose – ATP, – ADP, – Pi	Non-phospho form
Phosphorylase kinase		Phospho form
Glycogen phosphorylase	– Glucose – ATP – Glucose-6-P	Phospho form
Phosphofructokinase-1	+ Fructose-2,6-bisP + AMP – ATP, – Citrate	
Phosphofructokinase-2 (kinase)		Non-phospho form
Phosphofructokinase-2 (phosphatase)		Phospho form
Pyruvate kinase	+ Fructose-1,6-bisP	Non-phospho form
Pyruvate dehydrogenase complex		Non-phospho form
Pyruvate dehydrogenase kinases	+ Acetyl-CoA + NADH – Pyruvate, – CoA – ADP, – NAD ⁺	
Acetyl-CoA carboxylase	+ Citrate – Acyl-CoA	Non-phospho form
Pyruvate carboxylase	+ Acetyl-CoA	
Fructose-1,6-bisphosphatase	– Fructose-2,6-bisP – AMP	

'inactive' form or glycogen synthase 'b') is strongly inhibited by physiological concentrations of ATP, ADP, and Pi, but this inhibition can be overcome by glucose-6-phosphate. A non-phosphorylated 'I' form (Independent form or 'active form' or glycogen synthase 'a' form) does not require glucose-6-phosphate for its activity. PP-1, activated by the action of an insulin-dependent protein kinase, dephosphorylates the phosphorylated form of glycogen synthase ('D' form; inactive form) into an 'active' form ('I' form) (Figure 2), resulting in an increased flux through this enzyme. Binding of glucose (above 7 mM) to glycogen phosphorylase 'a' promotes its conversion from 'a' form to inactive 'b' form, resulting in its inactivation (and hence inhibiting glycogen degradation). Dephosphorylation of phosphorylase kinase and glycogen phosphorylase (Figure 2) results in the conversion of their 'active' forms into 'inactive' forms. Inactivation of glycogen phosphorylase results in release of PP-1 which then dephosphorylates phosphorylated glycogen synthase 'D' (inactive form) to its non-phosphorylated 'I' form (active form) stimulating glycogen synthesis (Figure 2).

PP-1 is active when it is associated with glycogen through its glycogen-binding G protein. G protein is subject to phosphorylation at two distinct sites: (1) phosphorylation of site 1 by an insulin-stimulated protein kinase activates PP-1 and (2) phosphorylation of site 2 (and also of site 1) by cAMP-dependent protein kinase A (PKA) results in its dissociation from glycogen-associated enzyme complex. In the cytosol, PP-1 inhibitor binds to PP-1, rendering it inactive. Interestingly, PP-1 inhibitor is also subject to phosphorylation (activation) by PKA and dephosphorylation (inactivation) by PP-1 (Roach *et al.*, 2012).

Furthermore, for a long-term regulation of glycogen synthase an intracellular signaling pathway mediated by insulin enhances transcription of the glycogen synthase gene, resulting in increased synthesis of this enzyme protein.

Regulation of the glycolytic pathway

The liver has a limited capacity to store glucose as glycogen (80–100 g) and hence the excess glucose-6-phosphate is processed via the glycolytic pathway and the hexose-monophosphate (pentose) pathway to generate eventually acetyl-CoA and NADPH to support lipid biosynthesis in the liver. The glycolytic pathway has two regulatory enzymes, namely phosphofructokinase-1 (PFK-1) and pyruvate kinase (Figure 1). PFK-1 (the first committed enzyme in the glycolytic pathway) is subjected to allosteric regulation by a number of molecules (namely fructose-2,6-bisphosphate, AMP, ATP, citrate, etc.). Among these allosteric modulators of PFK-1, fructose-2,6-bisphosphate, a product of phosphofructokinase-2 (PFK-2) derived from fructose-6-phosphate, is the most potent activator of PFK-1 (Figure 3) (Kurland and Pilkis, 1995). Interestingly, PFK-2 (which is a bifunctional enzyme with alternate functional kinase or phosphatase activity) is regulated by its covalent modification. Dephosphorylated PFK-2 protein possesses kinase activity, resulting in increased synthesis of fructose-2,6-bisphosphate which then acts as an activator of PFK-1 (Figure 3). In contrast, PFK-2 in its phosphorylated form expresses phosphatase activity and causes a breakdown of fructose-2,6-bisphosphate to fructose-6-phosphate (hence lowering the intracellular concentration of fructose-2,6-bisphosphate) (Figure 3). Hepatic PFK-1 is also subject to long-term regulation at the transcriptional level. Activity of

Figure 3 Regulation of glycolysis and gluconeogenesis at the level of PFK1 and F-1,6-bisP'ase. PFK1 uses ATP to convert F-6-P to F-1,6-bisP in the glycolytic pathway. F-1,6-bisP'ase catalyzes the hydrolysis of F-1,6-bisP to F-6-P in the gluconeogenic pathway. Flux in the direction of glycolysis is greatly increased by allosteric activation of PFK1 by F-2,6-bisP coupled with allosteric inhibition of F-1,6-bisP'ase by this same compound. PFK2 is a bi-functional enzyme that functions as a kinase for the conversion of F-6-P to F-2,6-bisP in its dephosphorylated state and as a phosphatase for the conversion of F-2,6-bisP back to F-6-P in its phosphorylated state. By signaling the dephosphorylation and therefore the activation of the kinase moiety of PFK2, insulin increases the level of F-2,6-bisP which stimulates glycolysis and inhibits gluconeogenesis. By signaling the phosphorylation (through PKA) and therefore the activation of the phosphatase moiety of PFK2, glucagon decreases the level of F-2,6-bisP which inhibits glycolysis and stimulates gluconeogenesis. AMP acts as an allosteric effector in manner similar to F-2,6-bisP, that is, it activates PFK1 and inhibits F-1,6-P'ase and ATP opposes stimulatory effect of AMP on PFK1. On the other hand, citrate allosterically increases the effectiveness of ATP as an allosteric inhibitor of PFK1.

pyruvate kinase is subject to regulation by all three mechanisms. Fructose-1,6-bisphosphate is an allosteric activator of (a feed-forward stimulation in the pathway) of liver pyruvate kinase (Table 1). This enzyme is also subject to a phosphorylation/dephosphorylation mechanism. Dephosphorylation of pyruvate kinase by PP-1 results in the conversion to its active form. Insulin-mediated transcription of the pyruvate kinase gene also plays a role in maintaining a steady state level of this enzyme in the liver. Collectively, the increased activities of three enzymes, namely glucokinase, PFK-1 and pyruvate kinase contribute to an increased flux in the glycolytic pathway (glycolysis) in the liver during the fed state.

Regulation of the pyruvate dehydrogenase complex

Pyruvate generated from glucose via the glycolytic pathway is transported by a carrier into the mitochondria where it is metabolized to acetyl-CoA and oxaloacetate by the PDC and pyruvate carboxylase, respectively. Dephosphorylation of

Figure 4 Regulation of the pyruvate dehydrogenase complex. PDC, a multi-enzyme complex found in the mitochondrial matrix space, is responsible for the oxidation of pyruvate to acetyl-CoA and CO_2 with concurrent reduction of NAD^+ to NADH. Subject to regulation by covalent modification, PDC is inactive in phosphorylated state catalyzed by PDKs (pyruvate dehydrogenase kinases) and active in the dephosphorylated state catalyzed by PDPs (pyruvate dehydrogenase phosphatases). Positive allosteric effectors of PDKs are given in green and negative allosteric effectors in red. One of the PDPs is allosterically activated by Ca^{2+} . Although the mechanism remains to be defined, insulin stimulates PDC activity by promoting PDP activity. PDKs and PDPs are integral proteins of the PDC complex.

Figure 5 Regulation of fatty acid synthesis at the level of acetyl-CoA carboxylase. ACC is responsible for the conversion of acetyl-CoA to malonyl-CoA for fatty acid synthesis. It exists in the liver cytosol as inactive monomers and large active polymers that are subject to inactivation by phosphorylation by PKA and AMP kinase (AMPK). By increasing cAMP, glucagon promotes inactivation of ACC and therefore inhibition of fatty acid synthesis. Likewise, an energy shortage that causes a fall in ATP and consequently an increase in AMP will also inactivate ACC and inhibit fatty acid synthesis. By signaling the activation of protein phosphatase-1 (PP-1), insulin promotes dephosphorylation and therefore activation of ACC and stimulates fatty acid synthesis. Allosteric inhibition of ACC by long-chain acyl-CoA esters is a good example of regulation of a pathway (lipogenesis) by feedback inhibition.

phospho-PDC by its specific pyruvate dehydrogenase phosphatases results in its activation resulting in increased formation of acetyl-CoA for the formation of citrate (Figure 4) (Harris et al., 2002; Patel and Korotchikina, 2003). Acetyl-CoA

also allosterically activates pyruvate carboxylase to increase oxaloacetate synthesis for citrate formation. A small portion of citrate is metabolized to CO_2 in the TCA cycle to form NADH and FADH₂ which are further processed via the respiratory chain and the oxidative phosphorylation pathway to generate ATP. The terms, the energy charge and phosphorylation potential, are generally used to calculate energy status of cells.

Regulation of fatty acid synthesis

The bulk of citrate is transported out to the cytosol to regenerate acetyl-CoA by the action of ATP-citrate lyase (dephosphorylated 'active' form). Acetyl-CoA in the cytosol is utilized for the synthesis of long-chain fatty acids (palmitate) (Figure 1) and cholesterol. ACC is the first committed step in the pathway of fatty acid synthesis, and is also subject to regulation by the three mechanisms (Figures 2 and 5). ACC in its monomeric form is inactive. Citrate enhances the formation of a polymeric, active form (a chain-like conformation) (Figure 5). Dephosphorylation of a polymeric form is the most active form and its dephosphorylation is carried out by PP-1 (Figure 5). For its long-term regulation, its gene transcription is up-regulated by the action of insulin-mediated signaling pathway (Figure 2). Activation of ACC increases the formation of malonyl-CoA which is further utilized by fatty acid synthase for the biosynthesis of long-chain fatty acids, palmitate (Figure 1). For the reductive synthesis of fatty acids, NADPH is also required. This requirement is met by the action of three enzymes, namely glucose-6-phosphate dehydrogenase, 6-phosphogluconate dehydrogenase, and NADP-malate dehydrogenase (aka malic enzyme) in the cytosol. The protein levels of these enzymes are regulated transcriptionally by the action of insulin (Owen *et al.*, 2012; Zoncu *et al.*, 2011). Increased levels of malonyl-CoA also act as an allosteric inhibitor of carnitine acyl-CoA transferase-I (McGarry, 1998) so that newly synthesized fatty acids (after conversion into their CoA derivatives) are not transported into mitochondria for oxidation but rather utilized for the synthesis of TAGs and incorporated into VLDL for transport. The separation of the pathway for fatty acid synthesis in the cytosol from the pathway of fatty acid oxidation in the mitochondria is a good example of cellular compartmentation for achieving metabolic regulation. The cytosolic pool of acetyl-CoA is also used for the synthesis of cholesterol in the liver. The key regulatory enzyme in this pathway is 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA) reductase which is subject to regulation by sterol-dependent regulation of its gene expression, sterol-accelerated enzyme degradation, covalent modification via a phosphorylation/dephosphorylation mechanism, and insulin-dependent up-regulation of its gene transcription. Hence, HMG-CoA reductase activity is increased in the fed state by its dephosphorylation and hence enhancing cholesterol synthesis in the liver. In the fed state, the newly synthesized TAGs and cholesterol are used for the synthesis of VLDL and transported into the blood. Liver also processes chylomicron remnants and reutilizes their TAGs for the formation of VLDL.

Protein synthesis

In the fed state, amino acids derived from dietary proteins are preferentially utilized for protein synthesis in the liver. Excess

amino acids are catabolized and their nitrogen is directed for urea synthesis. Acetyl-CoA derived from the degradation of carbon-skeletons of amino acids can be utilized for ATP production and/or lipid synthesis in the fed state. This, however, may represent a minor contribution to the total hepatic lipid synthesis.

Metabolism in the Fasted (Starvation) State

Fasted (starvation) state can arbitrarily be subdivided in three stages: (1) early fasted state, (2) intermediate fasted (starvation) state, and (3) prolonged fasted (starvation) state. Early fasted state is initiated after the post-absorptive period and continues for about 24–48 h after the last meal. There are metabolic changes which take place in tissues to maintain energy homeostasis and glucose homeostasis during this period (Cahill, 2006). Towards the end of the post-absorptive state as plasma glucose gradually returns to its basal level (~5 mM) so is the level of plasma insulin. During the early fasting state as the plasma levels of glucose and insulin continue to decrease, the plasma level of glucagon rises resulting in a reduction in the molar ratio of circulating insulin: glucagon ratio which favors the action of glucagon at the cellular level.

Action of Glucagon

Glucagon via interaction with its receptors (a G-protein coupled receptor, GPCR) increases synthesis of cAMP by adenylate cyclase, resulting in increased activity of cAMP-dependent protein kinase (PKA) (Figure 6). Increased PKA activity causes phosphorylation of the key regulatory enzymes in the metabolic pathways in the tissues (Berglund *et al.*, 2009; Harris and Crabb, 2010). This action increases the liver's capacity for glucose production by glycogenolysis and gluconeogenesis (Figures 1 and 6). The overall effect of this covalent modification is glycogenolysis since phosphorylation activates the key enzymes localized in the catabolic pathways (e.g., phosphorylase kinase and glycogen phosphorylase 'a') in the glycogen degradation pathway in the liver (Figure 6), and hormone-sensitive lipase in the TAG degradation pathway in adipose tissues. Glucagon increases glucose synthesis by promoting gene transcription and subsequent synthesis of gluconeogenic enzymes that include phosphoenolpyruvate carboxykinase (PEPCK) (Figure 6), F-1,6-bisphosphatase (F-1,6-bisPase), and glucose-6-phosphatase (G-6-Pase) (Figure 1).

Additionally, phosphorylation of the key enzymes (e.g., glycogen synthase, pyruvate kinase, ACC, etc.) in the biosynthetic pathways (Figure 6) results in inactivation of these enzymes to avoid futile cycling. The carbon-fluxes via the biosynthetic pathways (such as glycogen synthesis, fatty acid biosynthesis, and cholesterol synthesis) are markedly inhibited due to phosphorylation and hence inactivation of the key enzymes in these pathways (Figure 1). Protein synthesis is also markedly down regulated by reduction in insulin-mediated actions. Hence, this change in the plasma hormonal levels sets the direction from anabolic (biosynthetic mode) to catabolic state (degradative mode) in all tissues.

Figure 6 Glucagon promotes glucose production by glycogenolysis and gluconeogenesis. The glucagon signaling pathway involves activation of adenylate cyclase to produce cAMP which activates PKA (protein kinase A) by releasing an inhibitory protein. Active PKA promotes glycogen degradation by inactivating Gly syn (glycogen synthase) and activating Phos kinase (phosphorylase kinase) by phosphorylation. Active phosphorylase kinase activates Gly Phos (glycogen phosphorylase) by phosphorylation. Active PKA moves into the nucleus where it activates CREB (cAMP-responsive element-binding protein) by phosphorylation. Active CREB binds to the promoter of the PEPCK gene to promote transcription of the gluconeogenic enzyme PEPCK. Increased expression of PEPCK along with increased expression of other gluconeogenic enzymes increases the rate of gluconeogenesis.

Metabolism during Prolonged Starvation

After this period (~48 h) fasting extends into an intermediate starvation state lasting for about 2 weeks with major metabolic shifts in tissue fuel choices (Cahill, 2006). During this state the levels of plasma ketone bodies gradually rise to very high levels (in the range of 5 mM), resulting in increased transport and oxidation by the brain (due to high K_{ms} for ketone bodies by the monocarboxylic acid transporter). This shift allows the brain to meet its energy needs (to maintain energy homeostasis) but reducing its total dependency on glucose oxidation. This reduction in glucose demand by the brain coincides with reduction in the rate of hepatic gluconeogenesis from its precursors such as amino acids, glycerol, and lactate and pyruvate. Reduction in hepatic gluconeogenesis reflects in reduction in proteolysis in the skeletal muscle, a sparing effect on protein degradation. Selective fuel utilization in the brain oxidative metabolism from primarily glucose-dependent to a state of mixed fuel dependency (glucose plus ketone bodies) allows humans to survive for a much longer period of total starvation with a limited level of available protein mass (to support gluconeogenesis) and TAG mass in adipose tissues (to support energy homeostasis). During the prolonged starvation state (beyond about 2 weeks of starvation), this adaptive metabolic profile of the brain continues to operate with ketone bodies serving as major fuel

(approximately two-third of the energy needs) and glucose oxidation providing the rest. If starvation continues in this period, a continued demand on body fat and protein reserves cannot be met, leading to a catastrophic condition as death if feeding is not gradually initiated.

The normal American meal-eating pattern results in a re-occurring cycle of absorptive, post-absorptive and early fasted states. In a modern life-style with easily available foods, fasting beyond 24–48 h can only occur by predetermined reasons such as medical, religious, and occasionally political causes. Hence, in this section we will limit discussion on liver metabolism to the early fasting (starvation) state during the first 24–48 h.

Glucose Metabolism in the Liver (During Fasting)

Regulation of glycogen degradation

During the early fasted state the rates of glucose utilization by most tissues decrease (except the brain and tissues with anaerobic metabolism), and the rate of glucose release by the liver increases steadily due to breakdown of stored glycogen. The liver is the sole source of glucose provider for the rest of the body. The contribution to glucose release from hepatic glycogen gradually decreases after about 12 h of fasting and it is compensated by a gradual increase in the rate of hepatic gluconeogenesis during this period. After about 24 h of

fasting, liver glycogen is nearly depleted and the rate of glucose output by the liver is primarily supported by hepatic gluconeogenesis to maintain whole body glucose homeostasis. The rate of hepatic glycogenolysis is increased by phosphorylation (and hence activation) of its two regulatory enzymes, namely phosphorylase kinase and glycogen phosphorylase 'a' (Figure 6) (Roach *et al.*, 2012). These two enzymes are covalently modified by PKA which phosphorylates (and hence activates) phosphorylase kinase 'b' form to its 'a' form. Phosphorylase kinase 'a' then phosphorylates glycogen phosphorylase converting its 'b' (inactive) form into 'a' (active) form (Figure 6). This two-step activation cascade enhances rapid release of glucose from stored glycogen. Activities of these enzymes are also influenced by small molecules such as glucose, glucose-6-phosphate, and other compounds (allosteric effectors) (Table 1). Glucose-1-phosphate generated by this degradative pathway is first converted to glucose-6-phosphate and then to free glucose by glucose-6-phosphatase for its release from the liver.

Regulation of gluconeogenesis

Sources of gluconeogenic precursors are derived from different metabolic pathways: (1) lactate, pyruvate, and alanine are largely derived from inhibition of glucose-derived pyruvate oxidation by the PDC due to the metabolites (NADH and acetyl-CoA) generated from β -oxidation of fatty acids in the skeletal muscle, (2) glycerol generated from TAG breakdown by adipose tissues, and (3) release of gluconeogenic amino acids from proteolysis in the skeletal muscle. The carbon-skeletons of these amino acids are utilized for glucose synthesis and their amino-nitrogen is used for the synthesis of urea for nitrogen disposal. During the early state of fasting (about 24 h), all three sources contribute to glucose synthesis and its release by the liver.

Increases in hepatic cAMP levels also increase transcription of the PEPCK gene (Figure 6) (Yang *et al.*, 2009; Lin and Accili, 2011), resulting in a rapid accumulation of its enzyme protein within a few hours. Increased PEPCK activity together with increased availability of gluconeogenic precursors (such as lactate, pyruvate, and amino acid carbon-skeletons) results in an increased carbon-flux through this initial reaction in the gluconeogenic pathway (mitochondrial oxaloacetate to malate or aspartate and their transport to the cytosol via the malate/aspartate shuttles) for conversion to oxaloacetate and then to phosphoenolpyruvate (Figure 1). Phosphorylation and hence inactivation of hepatic pyruvate kinase in the cytosol and the PDC by its specific pyruvate dehydrogenase kinases (PDKs) in the mitochondria (Figure 4) direct the carbon-flux in the gluconeogenic pathway by inhibiting the former enzyme and minimizing the oxidation of the 3-carbon compound, pyruvate, by the latter enzyme complex (Harris *et al.*, 2002; Patel and Korotchikina, 2003). Additionally, phosphorylation of PFK-2 by PKA converts this bifunctional enzyme from its kinase activity to its phosphatase activity (Figure 3). PFK-2 (phosphatase) activity dephosphorylates fructose-2,6-phosphate to fructose-6-phosphate and hence lowers its intracellular concentrations and reduces its inhibition on fructose-1,6-phosphatase, a gluconeogenic enzyme, converting fructose-1,6-phosphate to fructose-6-phosphate. Glycerol derived from lipolysis in adipose tissues is

phosphorylated to glycerol-3-phosphate and then converted to dihydroxyacetone phosphate, a glycolytic intermediate. The final step in the gluconeogenic pathway is glucose-6-phosphatase which converts glucose-6-phosphate to glucose for its release. A long-term regulation of this enzyme is exerted at its transcriptional level.

Fatty acid oxidation and ketogenesis

This early fasting state is also characterized by increased mobilization of non-esterified fatty acids from TAGs breakdown (lipolysis) in adipose tissues. This results in increased levels of plasma non-esterified fatty acids, transported on serum albumin, which contribute to the energy demands (energy homeostasis) of liver, skeletal muscles, kidneys, heart, and other tissues by increased oxidation of fatty acids. This process also suppresses glucose oxidation and hence contributes to the maintenance of glucose homeostasis (Randle, 1998). Fatty acid oxidation via the β -oxidation pathway generates acetyl-CoA and reduced nucleotides (NADH and FADH₂), resulting in altered intramitochondrial acetyl-CoA/CoA ratio and also NAD⁺/NADH ratio, supporting gluconeogenesis and ketogenesis. Re-oxidation of these nucleotides via the respiratory chain and the oxidative phosphorylation pathway generates ATP to support gluconeogenesis. Acetyl-CoA acts as an allosteric activator of pyruvate carboxylase, an anaplerotic enzyme, converting pyruvate to oxaloacetate which is then converted to phosphoenolpyruvate by PEPCK. Both Acetyl-CoA and NADH act as activators of PDK (Table 1) (Harris *et al.*, 2002; Patel and Korotchikina, 2003) and cause phosphorylation/inactivation of PDC to conserve pyruvate for gluconeogenesis. During this period the liver also initiates the synthesis of ketone bodies (ketogenesis) from acetyl-CoA generated from fatty acid oxidation via the β -oxidation pathway. Ketone bodies are released by the liver, and are readily oxidized by several tissues (such as skeletal muscle, kidneys, heart, etc.) but not by the brain (due to its transporters with high K_ms for ketone bodies). The plasma levels of ketone bodies are maintained at a relatively low level (about 1–2 mM) during this early fasting state.

Dedication

This article is dedicated to Dr. Richard W. Hanson of Case Western Reserve University School of Medicine for his devotion and enormous contributions in the area of regulation of gluconeogenesis, for passionate teaching of metabolism, and for mentoring the next generation of investigators in the area of metabolic regulation. One of us (MSP) deeply acknowledges Dr. Hanson's generous mentorship, collegiality, and friendship over a period of 45 years.

Glossary

Free energy Description of energy that includes contributions from both physical forces and statistics.

Membrane electron transfer chain Organization of proteins containing electron transferring groups such as

hemes, in which the energetically downhill transfer of electrons is coupled to the transfer of protons across the membrane.

Energetics of Membrane-Based Adenosine Triphosphate Synthesis

The free energy available for the active processes of adenosine triphosphate (ATP) synthesis and active transport is derived from the transmembrane proton, or sodium, electrochemical potential gradient (Mitchell, 1979), written as $\Delta\tilde{\mu}_{H^+}$ for protons. The gradient consists of two components, (1) the difference in the concentration of protons, H^+ , between the two sides of the membrane, written as the pH gradient, ΔpH ; (2) the electrical potential, $\Delta\Psi$, across the membrane, expressed in volts or millivolts (mV), which results from the movement of uncompensated electrical charge across the apolar, hydrophobic, and low dielectric membrane. The proton electrochemical gradient, $\Delta\tilde{\mu}_{H^+}$, written in units of kcal mol^{-1} , is:

$$\Delta\tilde{\mu}_{H^+} = F\Delta\Psi - 2.3 RT \times \Delta pH \quad [1]$$

where F is the Faraday constant, $23 \text{ kcal mol}^{-1}\text{-volt}^{-1}$, and the coefficient $2.3RT = 1.36 \text{ kcal mol}^{-1}$. The free energy, ΔG , stored in the transfer on n protons across the organelle membrane is:

$$\Delta G = n \cdot \Delta\tilde{\mu}_{H^+} \quad [2]$$

Thus, in the case of the mitochondrial inner membrane, the thermodynamic contribution of the membrane potential, *ca.* -150 mV , inside (mitochondrial matrix) negative, tends to exceed that of the pH gradient, *ca.* 0.5 , inside more alkaline. Then, the free energy stored for each mole of protons translocated across the membrane from the matrix to extra-membrane domain, via coupling to the respiratory electron transport chain, is described by the following formula (ambient temperature, 25°C):

$$\Delta\tilde{\mu}_{H^+} = 23(0.15) - 1.36(-0.5) = +4.1 \text{ kcal mol}^{-1}$$

Based on structure studies of the extrinsic domain of the ATP synthase that defined three α - β pairs which contain the catalytic site in the F1 rotational nanomotor (Walker, 1998), and an intrinsic Fo sector with eight subunits in the c-ring of the bovine mitochondrial ATP synthase (Watt *et al.*, 2010), on the average $2.7H^+$ are utilized for the synthesis of one ATP molecule (Watt *et al.*, 2010), then the free energy utilized $= 4.1 \times 2.7 = 11.1 \text{ kcal mol}^{-1}$. This is greater than the standard free energy of ATP synthesis, which is approximately $7.5 \text{ kcal mol}^{-1}$ at pH 7 for the synthesis from ADP and

orthophosphate, and large enough to accommodate non-standard concentrations of these reactants.

For oxygenic photosynthesis in the chloroplast thylakoid membrane, the contribution of the ΔpH to the $\Delta\tilde{\mu}_{H^+}$ generated across the thylakoid membrane is believed to dominate the $\Delta\tilde{\mu}_{H^+}$. In a classical experiment that demonstrated the ability of an artificially generated $\Delta\tilde{\mu}_{H^+}$ in thylakoid membranes to drive the synthesis of ATP (Jagendorf and Uribe, 1966; Cramer and Knaff, 1991), a pH gradient of four units, inside negative, was shown to generate more than 1 ATP:10 Chl, a ratio more than one order of magnitude greater than the stoichiometry of the electron transport proteins in the membrane. The transmembrane potential across the thylakoid membrane can also contribute significantly to ATP synthesis (Sacksteder *et al.*, 2000). However, a major difference in the net free energy or $\Delta\tilde{\mu}_{H^+}$ requirement for ATP synthesis in chloroplasts expressed through either mode of energy storage was revealed by the structure analysis of the Fo sector of the chloroplast ATPase by atomic force microscopy. AFM analysis of thylakoid membranes data shows 14 and 15 c-subunits, respectively, in the intra-membrane Fo sector c-ring of the chloroplast (Seelert *et al.*, 2003) and cyanobacterial (Pogoryelov *et al.*, 2005) ATPase. Recalling that one rotation of the c-ring results in the synthesis of three ATP molecules, $4.7 (14/3)$ or $5H^+ (15/3)$ are utilized per ATP synthesized by the ATP synthetic mechanism associated with oxygenic photosynthesis. Referring to the calculation above for mitochondria, this implies that the $\Delta\tilde{\mu}_{H^+}$ required for ATP synthesis in chloroplasts is significantly smaller, $8/14$ or $8/15$, of that utilized in mitochondria. For chloroplasts, the requirement would be $(8/14) (4.1 \text{ kcal mol}^{-1}) = 2.3 \text{ kcal mol}^{-1}$, a value satisfied by a pH gradient, $\Delta pH = 1.7$, acidic inside the thylakoid lumen.

Atomic Structures of Membrane Protein Complexes Responsible for Energization, That Is, Generation of the $\Delta\tilde{\mu}_{H^+}$, of Mitochondria and Chloroplasts

There are three general processes or mechanisms for H^+ translocation known in energy-transducing membranes: (1) light-induced pK changes and resultant H^+ translocation, as in bacteriorhodopsin (Lanyi, 2004); (2) H^+ translocation coupled to electron transfer as in cytochrome oxidase (Yoshikawa *et al.*, 2012); or (3) oxidation/reduction of lipophilic quinol/quinone, as in (a) the cytochrome b_6f complex, and (b)

cytochrome bc_1 complex that function, respectively, in (a) oxygenic photosynthesis and (b) respiration or anoxygenic photosynthesis.

A Caveat

The pathways defined by crystal structures for proton transfer in the whole set of bioenergetic membrane proteins, and thereby the mechanisms for transmembrane proton transfer are in most cases still incomplete. The reasons for this gap are partly the complexity of the structures and partly lack of resolution in the structures. One aspect of the latter problem is that intra-membrane water is usually part of the transmembrane H^+ transfer chain, as described in the Grootthus mechanism (Cukierman, 2006). For the latter problem, the resolution of intrinsic waters, i.e., of the O atom of the water requires at the least a resolution in the quality of the diffraction pattern $\leq 2.5 \text{ \AA}$, a level that has not been achieved in the diffraction analysis of many crystallized membrane proteins. The system for which the pathway of H^+ transfer and generation of the membrane potential and proton gradient has been most clearly elucidated is that of bacteriorhodopsin, for which an array of high-resolution crystal structures has been obtained (Lanyi, 2004), in which an array of H_2O molecules have been shown to connect key carboxylate residues in the

pathway of transmembrane H^+ transfer driven by the light-induced retinal-based proton pump. Even here, the fundamental mechanisms by which the proton-carrying residues undergo a sequential increase and decrease in effective pK value, which allows these residues to act alternately as H^+ donors and acceptors, has not been described.

Primary Charge Separation and Formation of a Membrane Potential; Photosynthetic Reaction Centers

A primitive and fundamental mechanism for generation of the transmembrane potential, $\Delta\Psi$, is associated with the primary charge separation in photosynthetic reaction centers.

Reaction Center of Anoxic Photosynthetic Bacteria

The reaction center from the purple photosynthetic bacteria, *Blastochloris viridis*, documented in the protein data base (PDB) with PDB code 3T6D, is shown (Figure 1). The reaction centers are the long wavelength 'traps' to which light energy absorbed by the light-harvesting pigments is transferred, and which also serve as the interface between the processes of photosynthetic light harvesting and subsequent transmembrane electron transfer. This dimeric reaction center complex consists of four

Figure 1 Structure of the photosynthetic reaction center from the purple photosynthetic bacterium, *Blastochloris viridis* (Roszak et al., 2012). Left: The diagram shows the backbone polypeptide chain of a four heme cytochrome (yellow) that provides the electron donor to the reaction center, and the M ('medium,' purple), L ('light,' green), and H ('heavy,' orange) subunits, which contain 5, 5, and 1 transmembrane helices, respectively. The terms 'M', 'L', and 'H' refer to the relative positions of these subunits when they are separated by electrophoresis under denaturing conditions. Right: Prosthetic electron and proton transfer groups in reaction center: top, extra-membrane set of four hemes that function as the p-side electron donor to the complex; bottom, transmembrane electron transfer pathway in the dimeric structure from the 'special pair' electron donor (D_A , D_B) to the transmembrane pathway, via bacteriochlorophylls B_A and B_B , bacteriopheophytins (bacteriochlorophyll without the central Mg^{2+}), n-side electron and proton acceptors, quinones Q_A and Q_B . Figure 2 Photosynthetic electron transport chain in membranes that support oxygenic photosynthesis (Hasan *et al.*, 2013). Figure emphasizes the structures of the three hetero-oligomeric complexes in the chain: (a) the hetero-dimeric photosystem II complex (Figure 3); molecular weight of cyanobacterial PSII complex ≈ 350 kDa, containing 20 subunits, 35 chlorophyll molecules, 11 carotenoids, 14 lipids, 2 hemes, 1 non-heme iron, and the water-splitting Mn_4CaO_5 -cluster; (b) homo-trimeric photosystem I reaction center (trimer MW of cyanobacterial complex ≈ 1 MDa (Jordan *et al.*, 2001); 12 protein subunits and 127 cofactors comprising 96 chlorophylls, 2 phyloquinones, 3 Fe_4S_4 clusters, 22 carotenoids, 4 lipids, a putative Ca^{2+} ion, and 201 water molecules); monomer MW of plant complex ≈ 600 kDa (Amunts *et al.*, 2007), (c) the homo-dimeric cytochrome b_6f complex whose structure (Hasan *et al.*, 2013; Baniulis *et al.*, 2009; Cramer and Zhang, 2006; Hasan and Cramer, 2014; Kurisu *et al.*, 2003; Stroebel *et al.*, 2003; Yamashita *et al.*, 2007) is described below (Figure 4).

polypeptide subunits in the reaction center from the bacteria *Rhodospseudomonas viridis* (Deisenhofer *et al.*, 1984, 1995; Deisenhofer and Michel, 1989), and *B. viridis* (Roszak *et al.*, 2012), the L (light), M (medium), and H (heavy) subunits, which span the membrane, respectively, and a fourth subunit, a c-type cytochrome consisting four hemes, which serves as an electron donor to the complex (Figure 1). A structure of a three subunit complex, consisting of only the L, M, and H subunits was obtained from *Rhodobacter sphaeroides* (Allen *et al.*, 1987). Electrons are donated by the four heme cytochrome subunit to a bacteriochlorophyll dimer (the 'special pair,' 'P870,' referring to the wavelength of the absorbance peak, in *Rps. viridis*). Each monomer contains a p-side bacteriochlorophyll that is coordinated by a histidine residue (not shown) from transmembrane helix IV of the L- and M-subunits on the p- or cytochrome side of the complex. Light absorbed by the 'special pair' bacteriochlorophyll dimer drives electron transfer across the membrane to a quinone acceptor, with the initial transfer on a picosecond (10^{-12} s) time scale via a neighboring (several Å separation) bound bacteriochlorophyll and bacteriopheophytin to the quinone seen on the n-side boundary of the complex. The transmembrane electron transfer across the 30–35 Å hydrophobic domain generates a membrane potential, with a membrane specific capacitance of approximately $1 \mu\text{farad cm}^{-2}$, the transfer of one electron per 10^4 Å^2 generates a transmembrane potential, $\Delta\Psi$, on the order of 100 mV, negative on the side of the H subunit, where the quinone electron acceptor is seen. Electronic reduction of the quinone is concomitant with proton uptake to form the protonated reduced quinol, QH_2 , that functions in the transfer of protons across the membrane (see below, Pathways of Proton Transfer). The bacterial reaction center has also been solved to high resolution from the bacterium, *R. sphaeroides*, (Allen *et al.*, 1987), with similar and complementary structure information on electron charge transfer.

Reaction Centers of Photosynthetic Plants, Algae, and Cyanobacteria

The two photosystems responsible for charge transfer, oxygen evolution, and NADP^+ reduction/ CO_2 fixation in oxygenic photosynthesis are arranged in a linear electron transfer chain (Figure 2) in which electron transfer is initiated by water serving as the electron donor to the PSII reaction center. The PSII reaction center has been solved at a resolution of 1.95 Å (Suga *et al.*, 2015), which allowed a description of the Mn_4CaO_5 -cluster that catalyzes the oxidation of water to O_2 via redox intermediates of this cluster that support and define the four-step oxidation of H_2O to O_2 . The transmembrane electron transfer chain that carries the light-driven transport of electrons from water to a reaction center dimer ('P680') on the lumen or p-side of the complex and across the membrane to reduce plastoquinone on the stromal (n-side) of the membrane is structurally similar to the primary electron transfer chain in the photosynthetic bacteria (Figure 1) except that a chlorophyll and pheophytin in the system operating in plants, algae, and cyanobacteria replace the bacteriochlorophyll and bacteriopheophytin in the bacterial system. The arrangement of most of the 20 polypeptide subunits of the PSII reaction center along with the light-harvesting complexes, CP43 and CP47, is shown (Figure 3). The structure contains two polypeptide subunits in its core, D1 and D2, whose arrangement in the photosystem II reaction center complex is shown (Figure 3). The hetero-dimeric heme cross-linked cytochrome-b-559 (Widger *et al.*, 1985; Shinopoulos and Brudvig, 2012), drawn in purple in Figure 3, whose heme potential is dependent upon the hydrophobic environment in the membrane (Krishtalik *et al.*, 1993), is a PSII reaction center component whose function is not understood in the context of a linear electron transport function of the reaction center.

Figure 3 Monomer unit of the photosystem II reaction center complex. View of the PSII monomer from the luminal side normal to the membrane plane. Circles define the reaction core of the complex containing subunits D1, D2, PsbI, and PsbX, and separately the light-harvesting complexes CP43 and CP47. The dashed line defines the boundary of the monomeric unit in the dimer (Ferreira *et al.*, 2004). Reprinted with permission from Shinopoulos, K.E., Brudvig, G.W., 2012. Cytochrome b(5)(5)(9) and cyclic electron transfer within photosystem II. *Biochimica et Biophysica Acta* 1817, 66–75.

Reactions on the electrochemically positive p-side of the membrane support (1) the splitting of water (H_2O) to O_2 , and plastoquinol diffusion to the b_6f complex leading to reduction of the p-side [2Fe-2S] iron-sulfur protein (ISP), which supplies protons to the lumen (p-) side of the membrane and thereby contributes perhaps two-third of the protons derived from the linear electron transport chain, to the positive proton electrochemical potential. (2) Reduction of the ISP is followed by electron transfer to the heme of cytochrome *f* (not seen), then to the soluble copper protein plastocyanin or, in the presence of low copper concentrations, to a c-type cytochrome, either of which serves as a donor to the trimeric PSI, photosynthetic reaction center complex. (3) Photochemically driven electron transfer in the PSI reaction center across the membrane through an Fe and quinone electron transfer network reduces ferredoxin.

Reactions on the electrochemical n-side of the membrane: (1) Plastoquinone, PQ, in PSII, accepts electrons donated to the P680 special pair and transferred across the membrane on a picosecond–nanosecond time scale, and accepts protons (H^+) from the n-side aqueous phase, so that PQ is reduced to the hydrogen donor, PQH_2 . PQH_2 diffuses through the membrane bilayer to the b_6f complex. (2) Ferredoxin reduced by the PSI reaction center reduces NADP^+ to NADPH that is required for fixation of CO_2 . Ferredoxin can also be used in the ‘PSI cyclic electron transport pathway’ to feed electrons back to plastoquinone in the linear or ‘noncyclic’ electron transport

chain, with transfer via the b_6f complex (Zhang *et al.*, 2001), one possible pathway for closing the cyclic pathway (Figure 2).

Cytochrome b_6f Complex in Oxygenic Photosynthesis Provides Electronic Connection between the Two Reaction Center Complexes

The cytochrome b_6f complex (‘*f*’ for leaf; folium (latin)) (Figure 4), 270 kDa including lipids and prosthetic groups, connects the two photosynthetic reaction centers (Figure 3), and through its function in oxidizing hydrogenated plastoquinol, is coupled to proton translocation into the lumen-side aqueous phase and thereby mediates formation of most of the proton transmembrane electrochemical gradient, $\Delta\tilde{\mu}_{\text{H}^+}$, generated by the electron transport chain. The complex is a symmetric dimer that contains 13 TMH/monomer, 7 prosthetic groups ((5 redox, 4 hemes + 1 [2Fe-2S] cluster); 1 β -carotene, 1 chlorophyll *a*), and 23 lipid-binding sites/monomer. The b_6f complex is linked in evolution (Dibrova *et al.*, 2013; Nitschke *et al.*, 2010; Widger *et al.*, 1984; Schutz *et al.*, 2000) to the cytochrome bc_1 complex (Solmaz and Hunte, 2008; Esser *et al.*, 2004) that has similar functions in the mitochondrial respiratory chain and photosynthetic bacteria. There are specific differences in prosthetic group composition and structure that relate to some differences in detailed function. Four significant

Figure 4 Dimeric cytochrome b_6f complex in the cyanobacterium *Nostoc pcc 7120*. (a) Ribbon diagram shows the four major subunits, cytochrome f (cyan), cytochrome b_6 (yellow), ISP (pink), and SubIV (orange), and four smaller 'Pet' (Photosynthetic electron transfer) subunits, PetG (dark green), PetL (gray), PetM (light brown), and PetN (light green). (b) Semi-transparent diagram shows the positions of prosthetic groups, with redox (1) or other (2) functions: (1) hemes f and c_n (covalently bound c -type hemes), hemes b_p and b_n (non-covalently bound hemes on the p- and n-sides of the complex), and a [2Fe-2S] ISP. 'p' and 'n' denote the electrochemically positive (lumen) and negative (stroma) sides of the membrane. (2) the 20 carbon chain of a bound chlorophyll a molecule appears to control ('gate') access/exit of plastoquinol to the [2Fe-2S] center, the electron/proton acceptor of the quinol (Hasan *et al.*, 2014). The β -carotene has been proposed to function as a 'latch' (Hasan and Cramer, 2012) for a 'super-complex' formed with the photosystem I reaction center (Iwai *et al.*, 2010). Figure modified from Hasan, S.S., Yamashita, E., Cramer, W.A., 2013. Transmembrane signaling and assembly of the cytochrome b_6 -lipidic charge transfer complex *Biochimica et Biophysica Acta* 1827, 1295–1308.

differences in function involve the ability to (1) participate in ferredoxin-mediated cyclic electron transport and coupled phosphorylation (Zhang *et al.*, 2001; Arnon *et al.*, 1967), (2) support a transmembrane signaling mechanism that involves activation via p-side quinol oxidation of an n-side kinase activity that phosphorylates light-harvesting chlorophyll proteins (Vener *et al.*, 1997; Rochaix, 2014), (3) generate superoxide generated by plastosemiquinone reduction of molecular oxygen at a rate more than an order of magnitude greater than measured for the bc_1 complex (Baniulis *et al.*, 2013), and (4) from the affinity of quinone analogue inhibitors for the n- and p-side quinone-binding sites (Yamashita *et al.*, 2007; Hasan *et al.*, 2014).

The cytochrome b_6f complex as a lipoprotein

A relatively new perspective in structure–function of membrane proteins is that these proteins are not only surrounded by the lipid of the bilayer membrane, but lipid is also intercalated in hetero-oligomeric membrane proteins such as the mitochondrial cytochrome bc_1 complex (Hunte and Richers, 2008) and cytochrome oxidase (Shinzawa-Itoh *et al.*, 2007), the photosynthetic photosystem II reaction center (Guskov *et al.*, 2009), and the cytochrome b_6f complex (Hasan and Cramer, 2014; Figure 5). The functions of these intercalated lipids are presently a major area of investigation. The other basic set of questions that result from the new structure information on lipids in membrane proteins involves the mechanisms of the assembly of membrane proteins. The data and concepts about translocon function in membrane protein folding and assembly (Park and Rapoport, 2012; White and von Heijne, 2008) constitute a major advance. However, based on the now seemingly universal presence of lipids in the core of oligomeric membrane proteins, concepts of membrane protein assembly and folding must now take into account

Figure 5 Lipid-binding sites in the Cytochrome b_6f complex. From the 2.5 Å crystal structure of the cyanobacterial b_6f complex (Hasan and Cramer, 2014), 23 lipid-binding sites that mediate internal interactions in the complex were identified per monomer. The sites consist of a mixture of physiological lipids, synthetic lipid (DOPC) uniquely needed for crystallization (Zhang *et al.*, 2003), and detergent used for purification and crystallization: (1) the chlorophyll-binding site is stabilized by lipid; (2) the lipid, diacyl-glycerols, DAG7 (yellow/red sticks) and DAG8 (blue/red), interact with the subunit IV 'G' and 'F'-helices, (3) DAG7 also interacts with the single transmembrane helix of the PetG subunit in the outside 'picket fence.' Figure reproduced with permission from Hasan, S.S., Cramer, W.A., 2014. Internal lipid architecture of the hetero-oligomeric cytochrome b_6f complex. *Structure* 22, 1008–1015.

mechanisms for lipid insertion into membrane protein complexes.

Other functions associated with internal lipids are the following: (1) boundary lipids provide structure and perhaps

Figure 6 n-Side proton (H^+) uptake pathways of the b_6f complex. (a) The D (aspartate, Asp)-R (arginine, Arg) H^+ uptake pathway, described by a 2.70 Å structure (Baniulis *et al.*, 2009). An Asp20 → Arg207 route of H^+ transfer is described. (b,c) Arg207 as ligand to the quinone analogue inhibitors TDS (b) and NQNO (c), which mimic the physiological quinone, bound at the n-side quinone (Qn) binding site. Arg207 side chain interacts with the natural quinone bound at the Qn-site. Color code: heme b_p , brown lines; heme c_n , blue lines; TDS and NQNO, green-red-blue sticks; Peripheral Pet G, L, M, and N subunits and hydrocarbon tails of TDS and NQNO, not shown. (d) Potential H^+ uptake pathway mediated by water. Water 416 (red sphere) is coordinated by Arg207 backbone carbonyl oxygen and side chain, along with the propionate-A carboxylic acid group of heme c_n (blue). Wat416 is separated from the basic side chain of Lys24 in the cytochrome b subunit (cyan) by 4.6 Å. (e,f) E/D pathway of proton entry on the n-side of the complex. (e) In a 2.70 Å structure, Glu29 (subunit IV) located on the n-side surface of the complex interacts with a water molecule ('Wat,' red sphere), which forms a hydrogen bond with the acidic carboxylate side chain of Asp35 (subunit IV). (f) The Asp35 residue interacts with the quinone analogue TDS that is bound at the Qn-site. Transmembrane helices of cytochrome b (a–d) and subunit IV (e, f) are labeled. Reprinted with permission from Hasan, S.S., Yamashita, E., Baniulis, D., Cramer, W.A., 2013. Quinone-dependent proton transfer pathways in the photosynthetic cytochrome b_6f complex. *Proceedings of the National Academy of Sciences of the United States of America* 110, 4297–4302.

negative electrical charge adjacent to the β -carotene, whose 11 Å extension has been proposed to serve as a 'latch' to mediate super-complex formation (Iwai *et al.*, 2010) with the photosystem I reaction center complex and (2) structural interaction with the putative transmembrane kinase phosphorylates the light-harvesting chlorophyll protein for transmembrane signaling (Hasan and Cramer, 2012), and contributes to the dielectric heterogeneity that influences electron transfer between the transmembrane b -hemes in each monomer of the complex (Hasan *et al.*, 2014).

Structures, mechanisms, and mechanisms of H^+ transfer in the cytochrome b_6f complex

Understanding of the mechanisms of formation of the transmembrane proton electrochemical potential gradient requires an understanding of the intra-membrane and intra-protein pathways of proton transfer. As noted above, the energy-

transducing membrane protein for which these pathways have been mapped most completely is bacteriorhodopsin (Lanyi, 2004). Here, we discuss the pathways of H^+ transfer in the cytochrome b_6f complex. The fundamental mechanisms of transmembrane H^+ transfer discussed here for the b_6f complex, involvement of quinone/quinol, chains of protonatable amino acids, and water chains, also apply to the bc_1 complex.

Pathways of proton uptake into the membrane

As shown in Figure 6, the mechanism of transmembrane proton transfer utilizes quinone molecules, ubiquinone in the mitochondrial respiratory and photosynthetic bacteria bc_1 complex, and plastoquinone in oxygenic photosynthesis, as H^+ donor and acceptor, respectively, on the p- and n-side of the membrane. A unique aspect of these quinone-binding sites in mitochondria is that they can serve as binding sites for

Figure 7 p-Side H^+ exit pathway. Proposed proton exit pathway from the p-side binding niche of plastoquinol of the b_6f complex comprised of a hydrophilic portal (green), which is lined by the amino acids Glu78, Arg87 (cytochrome b_6), Ser91 (cytochrome b_6), Glu3 (PetG), and Asp58 (subunit IV). A broken arrow (black) marks the exit pathway of protons. Glu78 is connected to water 316 (wat316 in the figure) through a hydrogen bond that lies at the end of this portal. Tridecyl-stigmatellin (TDS), a quinone analogue inhibitor, has been inserted from the structure, PDB 2E76 (Yamashita *et al.*, 2007) to define the position of the Qp-site used by the physiological plastoquinone. Reprinted with permission from Hasan, S.S., Yamashita, E., Baniulis, D., Cramer, W.A., 2013. Quinone-dependent proton transfer pathways in the photosynthetic cytochrome b_6f complex. *Proceedings of the National Academy of Sciences of the United States of America* 110, 4297–4302.

quinone analogues that are antimalarials, for example, atovaquone at the p-side quinone-binding niche (Birth *et al.*, 2014), and a specialized pyridone class of inhibitors at the n-side quinone-binding site (Capper *et al.*, 2015).

Proton donation to the p-side aqueous phase; water intercalation into the cytochrome complex and the membrane

The bound TDS quinone analogue inhibitor marks the position that the plastoquinone occupies transiently while delivering two protons to the aqueous phase, one via a histidine residue of the p-side [2Fe-2S] protein and the other through the glutamic acid residue, Glu78 (Figure 7), to a nearby water marked by water oxygen 316. Lipophilic quinone has a central role in proton translocation in the cytochrome b_6f and bc_1 complexes. The mechanism, the 'Q cycle' is particularly well documented for the mitochondrial and photosynthetic bc_1 complex (Mitchell, 1975, 1979; Berry *et al.*, 2000; Crofts *et al.*, 2008; Cooley *et al.*, 2009).

The intrusion of water, shown in Figure 7, into membrane proteins has been noted in other membrane transport proteins, for example, the bc_1 complex (Solmaz and Hunte, 2008) and the lactose transporter (Kaback, 2004), and may have a universal function in these proteins in facilitating the transfer of protons across part of the membrane.

The Mitochondrial Respiratory Chain

Central properties of the respiratory chain shown in Figure 8 are:

1. The maximum number of H^+ translocated across the membrane from the n (matrix)-side to the p-(cytoplasmic) side of the membrane for each two electrons transferred through the electron transport chain, from the maximally reducing end (NADH dehydrogenase) of the electron transport chain, to the oxidizing end at which O_2 is reduced

Figure 8 Electron and proton transfer complexes of the respiratory chain in bovine mitochondria summarized in Hosler *et al.* (2006). These complexes include the NADH dehydrogenase, succinate dehydrogenase (pdb, 1NEN), cytochrome bc_1 complex (pdb, 1PP9), cytochrome c oxidase (pdb, 1V54); and Q, lipophilic ubiquinone/ol. Reprinted with permission from Hosler, J.P., Ferguson-Miller, S., Mills, D.A., 2006. Energy transduction: Proton transfer through the respiratory complexes. *Annual Review of Biochemistry* 75, 165–187, updated by S. Ferguson-Miller.

Figure 9 Structure of the mitochondrial complex I from *Y. lipolytica*. Ribbon diagram of L-shaped structure of NADH:ubiquinone oxidoreductase (complex I) from peripheral arm (a) and (b) rotated 90°. Accessory subunits are shown in gray. (c) Arrangement of cofactors in the peripheral arm. Center-to-center and edge-to-edge (in brackets) distances are in angstroms. Reprinted with permission from Zickermann, V., Wirth, C., Nasiri, H., *et al.*, 2015. Structural biology. Mechanistic insight from the crystal structure of mitochondrial complex I. Science (New York, NY) 347, 44–49.

to H_2O in the cytochrome oxidase is 10 (i.e., $\text{H}^+ / 2\text{e}^- = 10$ for the respiratory chain).

- The other parameters associated with mitochondrial energy transduction and ATP synthesis are the specific efficiency of ATP production in the total electron transport chain initiated by the oxidation of NADPH, which is approximately 2.8 ATP/2e⁻ (Hinkle, 2005), if the average stoichiometry of H^+ utilization associated with ATP synthesis is 2/3 (8/3) H^+ utilized per ATP synthesized (Watt *et al.*, 2010) by the 'F1-Fo' rotational nanomotor (Walker, 1998; Junge *et al.*, 2009). A different perspective on the organization of the mitochondrial respiratory chain, obtained from analysis of the entire chain and sub-complexes is that it is organized as a 'super-complex' (Althoff *et al.*, 2011). Although this structure perspective needs verification, particularly with respect to gaps between the individual complexes, it has the conceptually important perspective that it solves the problem of inter-complex connections which, in the 'classical textbook models' (e.g., Figure 8) involves random diffusion of quinone within the membrane, and of cytochrome *c* at the external p-side interface, to electronically connect the complexes.
- Complex I, or NADH dehydrogenase, is at the reducing end of the respiratory chain. The eukaryotic (e.g., human) (Zickermann *et al.*, 2015) and bacterial (NDH-1) (Baradaran *et al.*, 2013) NADH dehydrogenase ('complex I') contain 45 subunits and 16 subunits, respectively. The overall proton/electron stoichiometry for proton translocation in complex I is $\text{H}^+ / 2\text{e}^- = 4$. Of all the mitochondrial proton-translocating complexes, the intra-protein mechanism of proton translocation is least well understood in complex I.

Complex I, NADH dehydrogenase

Atomic structures of the entire complex I (536 kDa, 16 subunits, 9 Fe-S clusters, 64 TM helices) have been obtained from the bacterium, *Thermus thermophilus* (Baradaran *et al.*, 2013) (536 kDa, 16 subunits, 9 Fe-S clusters, 64 TM helices), and from the yeast model, *Yarrowia lipolytica* (Figure 9); for the eukaryotic complex, defects in complex I are responsible for the majority of mitochondrial-based diseases (myopathies), presumably because this complex is operating at the most negative oxidation–reduction potential (midpoint oxidation–reduction potential of $\text{NAD}^+ / \text{NADH}$ at pH 7 = −0.32 V) in the respiratory chain, with which it can reduce O_2 to superoxide (oxidation–reduction potential = −0.15 V). The NADH oxidation site is at the exterior of the long (>100 Å) peripheral domain (panel C) extending from the n- or matrix side of the membrane. This extension contains eight iron–sulfur clusters that transfer electrons from NADH to the ubiquinone that is approximately 20 Å from the membrane interface and, somewhat surprisingly not positioned well into the hydrophobic membrane. The structure suggests a unique coupling mechanism, with redox energy of electron transfer driving proton translocation via long range (up to ~200 Å) conformational changes. It resembles a steam engine, with coupling elements (akin to coupling rods) linking parts of this molecular machine. A continuous axis of basic and acidic residues running centrally through the membrane arm connects the ubiquinone reduction site in the hydrophilic arm to four putative proton-pumping units.

Cytochrome *bc₁* Complex

Many of the structure–function aspects of the cytochrome *bc₁* complex discussed above in the context of Figures 4–7

Figure 10 Structure and cofactor arrangement in cytochrome caa₃-oxidase (Lyons *et al.*, 2012). (a) Structure (ribbon model). SU I/III colored as: SU I, blue; SU III, blue-gray and the fusion linker, dark blue. SU IIc colored to highlight the classical SU II (red) and the fused cytochrome *c* domain (green). SU IV in yellow. Hemes in ball and stick with the iron and copper metal centers as gray and copper spheres, respectively. Membrane boundaries based on hydrophobic thickness calculations from the OPM server31. (b) Cofactor arrangement. Hemes *c*, *as*, and *as*₃, and the iron and copper ions shown as in (a). Mg²⁺ represented as light blue sphere. Distances, in brown. SU I/III, IIc, and IV are color-coded as faded blue, red, and yellow ribbons, respectively. Reprinted with permission from Lyons, J.A., Aragao, D., Slattery, O., *et al.*, 2012. Structural insights into electron transfer in caa₃-type cytochrome oxidase. *Nature* 487, 514–518.

apply to the similarly but, by far, not identically connected *bc*₁ complexes, which have been discussed separately for the mitochondrial (Berry *et al.*, 2013) and bacterial (Crofts *et al.*, 2008; Esser *et al.*, 2008) electron transport chains, and also compared with the *b*₆*f* complex (Cramer *et al.*, 2011).

Cytochrome Oxidase

Cytochrome *c* oxidase functions as the terminal enzymes in the respiratory chain of mitochondria and aerobic prokaryotes, coupling molecular oxygen reduction to transmembrane proton pumping. The enzyme's function is the transfer of electrons from cytochrome *c* to the oxidase via a transient association of the two proteins. The crystal structure shown in Figure 10, is the caa₃-type cytochrome oxidase from *Thermus thermophilus*, which has a covalently tethered cytochrome *c* domain (Lyons *et al.*, 2012).

Acknowledgments

The authors' studies associated with the composition of this manuscript were supported by U.S. NIH grant GM-038323, and significantly aided by discussions with Dr. S. Saif Hasan.

Glossary

aaRS Aminoacyl-tRNA synthetase include 22 members one for each amino acid in general.

AAS Amino acid accepting stem of tRNA.

AA-tRNA Aminoacyl-tRNA generated by aminoacyl-tRNA Synthetase through conjugation of amino acid with the 3'-OH of tRNA.

Amber codon UGA, a normal termination codon, but also be used to encode pyrrolysine (Pyl) or selenocysteine (Sec) in many species.

Aminoacyl-AMP Amino acyl adenosine monophosphate, a high energy reaction intermediate generated by aaRS by activating amino acid using ATP.

ASL anticodon stem loop of tRNA.

ATF4 Activating transcription factor 4 (tax-responsive enhancer element B67).

Aza-IP 5-Azacytidine-mediated RNA immunoprecipitation.

CCA-adding enzyme ATP(CTP):tRNA nucleotidyltransferases, add CCA onto the 3' end of tRNA precursors without using a nucleic acid template.

CHOP DNA damage-inducible transcript 3, also known as C/EBP homologous protein (CHOP), is a transcription factor downstream of GCN2.

Class I aaRS Class I aaRS whose aminoacylation domain has a typical Rossmann fold, including ArgRS, CysRS, GluRS, GlnRS, IleRS, LeuRS, LysRS-I, MetRS, ValRS, TrpRS, and TyrRS.

Class II aaRS Class II aminoacylation domain has 7 β -strand sheet fold, including AlaRS, AsnRS, AspRS, PheRS, GlyRS, HisRS, LysRS, ProRS, SerRS, ThrRS, and PylRS.

Class I tRNA Majority of tRNAs, contains regular variable loop region.

Class II tRNA tRNAs containing long variable loop region, include tRNA^{Leu}, tRNA^{Ser}, tRNA^{Sec}, and bacterial tRNA^{Tyr}.

Editing/proofreading domain Independent structure containing a hydrolytic site for removing the incorrect aminoacyl-tRNA, existing either in the same aaRS or in a freestanding editing enzyme.

eEF1 Eukaryotic elongation factor 1, formed by eEF1-alpha-beta-gamma. eEF1-alpha is the eukaryotic equivalent of EF-Tu; eEF1-beta-gamma are eukaryotic equivalents of EF-Ts.

eEF2 Eukaryotic elongation factor 2, is the equivalent of prokaryotic EF-G and regulates ribosome translocation.

EF-G Elongation factor G, catalyzes the recycling of ribosomes after one round of protein synthesis.

EF-Ts Elongation factor thermo stable in bacteria.

EF-Tu Elongation factor thermo unstable in bacteria.

eIF2 eukaryotic initiation factor 2, contains eIF2 $\alpha/\beta/\gamma$.

eIF2 $\alpha/\beta/\gamma$ bound to GTP delivers the initiator methionyl-tRNA (Met-tRNA^{iMet}) to the small ribosomal subunit in the first step of translation.

eIF2B Guanine exchange factor (GEF) of eIF2.

GCN2 General control nonderepressing 2 protein kinase (GCN2) as the primary sensor of amino acid starvation.

GCN4 General control nonderepressing 4 protein in yeast. GCN4 is the primary regulator in response to amino acid starvation, termed general amino acid control (GAAC). It acts as a transcription factor and activates several genes required for amino acid synthesis.

Identity element Nucleotide acid on tRNA that is responsible for the correct recognition of tRNA by the corresponding aaRS, or features that is rejected by the inappropriate aaRSs.

Initiation codon Protein synthesis in general starts with an AUG codon near the beginning of the mRNA, following the 5'-UTR, which often contains regulator elements for translation control.

Mischarged tRNA An incorrect amino acid linked to the tRNA.

mt-tRNA Mitochondrial tRNA – tRNAs that are encoded in mitochondrial genome.

N-end rule A rule states that the N-terminal amino acid of a protein determines its half-life. The rule applies to both eukaryotic and prokaryotic organisms, but with different strength.

Peptidyl-tRNA An intermediate product during peptide synthesis. It transfers the growing polypeptide to the aminoacyl-tRNA bound in the A/A site, is bound in the P/P site.

Post-editing Proofreading hydrolysis of incorrect aminoacyl-tRNA in a separate editing domain, either in the same aaRS, or in a free-standing editing enzyme.

Pre-editing Proofreading hydrolysis of incorrect aminoacyl-AMP in the same catalytic site prior to its transfer to 3'-OH of tRNA.

RNase P A type of ribonuclease which cleaves off an extra sequence of RNA on the 5' leader sequence of precursor tRNA.

RRFs Release factors (RFs) or ribosomal recycling factors (RRFs) recognize the termination codons and terminate translation.

tDNA Gene encoding tRNA.

tmRNA Transfer-messenger RNA (abbreviated tmRNA, also known as 10Sa RNA and by its genetic name SsrA) is a bacterial RNA molecule with dual tRNA-like and messenger RNA-like properties.

Termination codons Three stop codons (UAA, UAG, and UGA) signaling a termination of translation in mRNA.

TLS Certain positive-strand RNA plant viral genomes possess 3'-tRNA-like structures (TLSs) that are built quite differently from authentic tRNAs.

Wobble base pair is a pairing between two nucleotides in RNA molecules, other than the Watson–Crick base pairs. The four main wobble base pairs are guanine–uracil (G–U), hypoxanthine–uracil (I–U), hypoxanthine–adenine (I–A), and hypoxanthine–cytosine (I–C). The thermodynamic stability of a wobble base pair is comparable to that of a Watson–Crick base pair.

Wobble position A position in the 5' anticodon of tRNA. In the wobble position a G can base-pair with the two corresponding codons that have either pyrimidine (C or U) in the third position.

Basis of Transfer RNA

Transfer RNA (tRNA) is a short nucleotide RNA chain, about 80 nucleotides, which carries specific amino acids to the ribosome for addition to growing polypeptide chains during translation. tRNA functions as an 'adaptor' molecule that mediates the recognition of three nucleotide codon sequences in the messenger RNA (mRNA) and allows suitable amino acid translation of that codon. tRNAs contain a single stranded loop that base pairs with mRNA codon sequences and a CCA nucleotide sequence at the 3' end for connecting to specific amino acids. Francis Crick first proposed the hypothesis of an adaptor molecule that recognizes amino acid-related mRNA sequence and provides the appropriate amino acid for protein synthesis (Crick, 1958).

tRNA and genetic code

tRNA is the key to deciphering the genetic code in mRNA. Each amino acid has its own subset of tRNAs, which are attached to the amino acid and carry it to the growing end of a polypeptide chain. The tRNA contains a three-nucleotide sequence, an anticodon, that base pairs with its complementary codon in the mRNA (Crick, 1968; Chapeville *et al.*, 1962). tRNA anticodons are read in the 3'→5' direction to match the mRNA codons that are read in the 5'→3' direction. For example, if the anticodon base sequence is 3'-AAG-5', the corresponding codon in mRNA is 5'-UUC-3'. There are 64 potential codons (4³), 61 of these (in general) are recognized by tRNAs and encode for amino acids while 3 function as termination codons (Figure 1).

In 1966 Francis Crick proposed the wobble hypothesis to explain the observed degeneration in the third position of mRNA codons (Crick, 1966). He proposed that the 5' base of tRNA anticodon ('Wobble base') is spatially less constricted than the other two bases and can make non-standard base pairing with the 3' end of the mRNA codon. The first two bases of an mRNA codon always makes powerful Watson–Crick base pairing with tRNA anticodon while there is flexibility in the third position relieving the obligation to obey base-pairing rules. In this regard the G•U base pair is particular important since G•U structurally fits almost as well as the G•C pair. A given anticodon in tRNA with G in the 5' (wobble) position can base-pair with the two corresponding codons that have either pyrimidine (C or U) in the third position. For example, the phenylalanine codons UUU and UUC (5'→3') are both recognized by the tRNA that has AAG (3'→5') as the anticodon. Because of this, codons of NNU and NNC always encode the same amino acid and are decoded by a single tRNA with NNG anticodon (with G in the 5' wobble position).

tRNAs containing inosine in the wobble position have the greatest variability in codon recognition. Inosine is a deaminated product of adenine and therefore does not contain an amino group at the 2' carbon atom. In the 5' wobble position of tRNA anticodons, inosine can match with cytosine, uracil, or adenine. For example, a tRNA whose anticodon is CCI, will fit with GGU, GGC or GGA mRNA codons and add glycine to the growing protein chain. According to this hypothesis, 61 different anticodons (or 61 different tRNAs) are not needed to decode the 61 mRNA codons (Crick, 1966; Varani and McClain, 2000) and in fact, many cells contain fewer than 61 tRNAs.

Figure 1 The genetic code. The correspondence between each of the 4³ (64) possible codon-triplets and the 20 amino acids of cellular proteome (22 in some organisms) is called the genetic code. Of the 64 codons, 61 are usually sense codons. Most of these are organized in so-called degenerated codon family boxes where synonymous triplets code for the same amino acid. Only a few codons are unassigned, usually UAA, UAG and UGA that are used as termination codons. UAG also codes for the 21st amino acid Sec (selenocysteine) or 22nd amino acid Pyl (Pyrrolysine) in some species (a). (b) The three possible reading frames in protein synthesis. In translation, the sequence of nucleotides in an mRNA molecule is read from the 5' end to the 3' end in consecutive sets of three nucleotides (blue), where in principle, the same RNA sequence can specify three completely different amino acid sequences (red). However, in most cases, only one of these reading frames is decoded by tRNA and contains the actual message. (c) The genetic code is read through a matching between anticodon of tRNA and the codon of mRNA, where 1st and 2nd position are conventional base pair. The 3rd, or wobble position is less stringent.

Figure 1 shows that most amino acids are encoded by more than one codon. Only two, methionine and tryptophan, have a single codon, while leucine, serine, and arginine each have six different synonymous codons.

The amino acid specified by each codon is conserved in most known organisms with a few exceptions. In many mitochondria, ciliated protozoans and in a single-celled plant called *Acetabularia* there is some divergence, however, in most other cases this involves reading of a normal stop codon (amber codon) as an amino acid codon and not an exchange of one amino acid for another. For example, in all three kingdoms, amber stop codon in a few mRNAs, followed by a specific sequence in the 3' untranslated region (3'-UTR, in archaea and eukarya) or in the following reading frame (bacteria) are

recognized by a specific tRNA for selenocysteine (Sec, the 21st amino acid). There are 25 proteins containing Sec in human.

A special case of codon use is found with the cytoplasmic tRNA^{Met}. Nuclear genomes of all eukaryotes contain two genes coding for two different types of tRNA^{Met} (eMet and iMet), which both harbor the UAC anticodon. One gene (often in multicopy) encodes the elongator tRNA (tRNA^{eMet}) and is used for incorporating internal methionines, while the other gene encodes the initiator tRNA (tRNA^{iMet}) and is used for initiating the synthesis of the polypeptidic chain. Although both cytoplasmic tRNA^{Met}s are charged by the same cognate Met-tRNA synthetase (MetRS), their sequences are markedly different. Indeed, the specific role of tRNA^{iMet} is highlighted by the conservation of a number of sequence features that make it

Figure 2 A tRNA molecule. The structure of yeast phenylalanyl tRNA is illustrated in open 'cloverleaf' form (a, b) to show complementary base pairing. Modified bases are indicated as mG, methylguanosine; mC, methylcytosine; DHU, dihydrouridine; T, ribothymidine; Y, a modified purine (usually adenosine); and ψ , pseudouridine. The folded form of the molecule is shown in (c) and a space-filling model in (d).

the most widely conserved tRNA throughout the three kingdoms of life (Marck and Grosjean, 2002; Grosjean *et al.*, 2010). In yeast *Saccharomyces cerevisiae*, the 2'-O-ribosyl phosphate modification at position 64 of tRNA^{Met} also serves for discrimination between the tRNA^{iMet} and the elongator tRNA^{eMet} (Astrom and Bystrom, 1994). Thus the same codon, AUG, depending on its location in the coding sequence, is used for two different purposes yet for the same amino acid. Therefore, the actual number of different codons for the 20 amino acids in any eukaryotic cell is not 61, but 61 + 1, as the two iMet and eMet codons are read by two different tRNAs.

Two Classes of tRNAs

The function of tRNA molecules is dependent on their unique three-dimensional structures. Since the first *S. cerevisiae* tRNA^{Phe} was determined by X-ray analysis (Kim *et al.*, 1974; Robertus *et al.*, 1974), nearly 200 structures of tRNAs and their fragments have been determined (Giegé *et al.*, 2012; Abe *et al.*, 2011). All tRNA molecules fold into a similar cloverleaf-like stem-loop arrangement (Figure 2). The four stems are short double helices stabilized by Watson–Crick base pairing; three of the four stems have loops containing seven or eight bases at their ends, while the un-looped stem contains the free 3' and 5' ends of the tRNA (amino acid accepting stem, AAS). The three nucleotides composing the anticodon are located at the center of the middle loop (anticodon stem loop, ASL) in an accessible position that facilitates codon-anticodon base pairing. All tRNAs are first transcribed into a precursor tRNA and several processing steps are required to convert the precursor transcript into a properly folded, functional tRNA molecule. A ribozyme (RNase P) is responsible for the generation of the mature 5'-end of tRNAs. The removal of tRNA 3' sequences is done by an endonuclease cleaving immediately 3' to the last nucleotide of the tRNA gene. All tRNAs contain a CCA sequence at the 3' end and this is usually added after synthesis and processing of the tRNA by CCA-adding enzyme (Jackman and Alfonzo, 2013; Heinemann *et al.*, 2010; Schurer *et al.*, 2001; Wolin and Matera, 1999). Several bases in tRNAs are also commonly modified after synthesis and this is important for proper folding into the tertiary structure (Giegé *et al.*, 2012; Wolin and Matera, 1999), which has a characteristic L shape with the anticodon loop and acceptor stem at each end (Figure 2).

Therefore, the canonical cloverleaf tRNA can be divided in six subdomains, 1) AAS of 7 bp (base pair) terminated at the 3' strand by $-N_{73}CCA_{OH}$ (N_{73} being the discriminator, N for any nucleotide) and at the 5' strand pN_1 (additional N_{-1} in tRNA^{His}); 2) A 2 nt (nucleotide) connector (U_8, U_9) between AAS and DSL; 3) DSL (D-stem loop of tRNA; N_{10} to N_{25}), a 4 bp stem closed by 7–11 nt D-loop (With A_{14}, R_{15} , and a variable content of Dihydrouridines located 3' or 5' of conserved $G_{18}G_{19}$); 4) ASL (N_{27} to N_{43}), a 5 bp stem and a 7-nt loop (with U_{33}, R_{37} and the anti-codon triplet N_{34}, N_{35}, N_{36} ; R for purine); 5) V (variable region; N_{44} to Y_{48}) of 4 to 24-nucleotides; 6) TSL (T-Stem Loop, T_{54} to N_{60}) with a 5 bp stem (53–61 with a conserved G-C base pair) and a 7-nt loop (with $T_{54}, \psi_{55}, C_{56}, A_{58}$).

Canonical tRNAs are divided into two classes depending on the size of the variable region (N_{44} to Y_{48} ; Figure 3). Class I tRNAs contains small variable region (4–5 nucleotides) and

includes most of the tRNAs (Giegé *et al.*, 2012; Hall *et al.*, 1989). Class II tRNAs are characterized by a large variable regions and include tRNA^{Leu}, tRNA^{Ser}, tRNA^{Sec}, and bacterial tRNA^{Tyr}. The variable region in class II tRNAs forms a stem-loop structure and ranges in size from 15 to 24 nucleotides. Further, the D-stem is 13–22 bp in class II tRNAs versus 4 bp in class I tRNAs. These large variable regions are often used for recognition by the corresponding aminoacyl-tRNA synthetases.

The L-shaped architecture of both classes of canonical tRNAs is formed by two helical domains of 12 base pair each. These two helical domains are held together by similar tertiary interaction networks at the elbow position and involve 12 conserved or semiconserved bases ($U_8, Y_{12}, A_{14}, R_{15}, G_{18}, G_{19}, R_{20}, R_{23}, Y_{48}, \psi_{55}, C_{56}$, and R_{57}). These bases form a high packed core with seven layers that corner the L-shaped structure at the D- and T-loops. The seven layers are stacked in the order of $Y_{48} \bullet R_{15}$ Levitt trans W-C pair; $A_{21} (A_8 \bullet U_{11})$ triple base; $R_{46} \bullet (N_{22}-N_{13})$; $R_9 \bullet (R_{23}-Y_{12})$ base pair $N_{24}-N_{11}$ base pair; $N_{45} \bullet (N_{10}-N_{25})$ base pair; $R_{33} \bullet R_{26}$ base pair. The D-loop and T-loop is further connected by $G_{19} \bullet G_{56}$ Watson–Crick base pair, atypical H-bonding of ψ_{55} with G_{18} and stacking of R_{57} with G_{18} and G_{19} . Note that $N_{45} \bullet N_{10}$ and $R_{46} \bullet N_{22}$ are missing in class II tRNAs.

One exception to canonical tRNAs is the tRNA for pyrrolysine (tRNA^{Pyl}), the 22nd amino acid. Pyrrolysine (Pyl) is a natural, genetically coded amino acid used by some methanogenic archaea and bacteria, with a UAG 'amber' stop codon (Krzycki, 2005). While tRNA^{Pyl} exhibits a rather canonical L-shape, tRNA^{Pyl} lacks many of the invariant structural elements conserved in the canonical tRNAs (Nozawa *et al.*, 2009). The most prominent differences include an elongated anticodon stem of six base pairs instead of five; one nucleotide at the junction connecting the acceptor and D-stem, instead of two; a short variable region of only three bases; a small D-loop of only five bases; absence of the universally conserved $G_{18}G_{19}D_{20}$ (D-loop) and $T_{54}\psi_{55}C_{56}$ (T ψ C-loop) sequences and absence of the conserved modifications, such as m^2G_{26} , m^7G_{46} and D_{47} . The resulting tertiary interactions between the non-standard D-arm, the T ψ C-loop and variable region are so different that tRNA^{Pyl} has a quite compact core structure with re-organized tertiary base pairs (Figure 3). Therefore, the structure of tRNA^{Pyl} represents an interaction pattern that is rather idiosyncratic to the tertiary structure of all other tRNAs.

Paralogous tRNA Genes/tRNA Isoacceptors

The wobble base in tRNAs and codons enables a single tRNA to recognize several codons so that although there are a maximum of 61 amino acid codons, not every codon has a unique tRNA and the total number of tRNAs in one species can be degenerated to less than 61 (this is usually seen in organelles). Vice versa, several different tRNA genes may contain the same anticodon sequence but be slightly different in the rest of the sequence. An example of the variability of tRNA gene number is demonstrated by comparing *Escherichia coli*, which has 88 tRNA genes (tDNA), with humans, which have 647 tRNA genes (625 cytoplasmic tRNA genes and 22 mitochondrial tRNA genes). Ranges from 1 to 600 tDNAs per amino acid and 0.3–200 per codon are seen across species (Table 1).

Figure 3 Two classes of tRNA. The standard L-shaped 3D-structure of class I tRNAs represents a majority of tRNAs as shown in the *Sce* tRNA^{Asp} (pdb2tra, a) versus the long various loop containing class II tRNA as shown in the *Tth* tRNA^{Ser} (pdb1ser, b). The atypical tRNA^{Pyl} represents a shape idiosyncratic to other tRNAs (pdb2zni, c).

Table 1 Statistics of number of tRNA genes in different organisms

Organism	Total number of tRNA genes	Total number of decoding amino acid	Average number of tRNA gene/codon	Average number of tRNA gene/amino acid	Maximum number of tRNA gene/amino acid	Kingdom
<i>Pyrococcus abyssi</i>	46	46	0.72	2.3	5	Archaea
<i>Escherichia coli</i>	88	87	1.36	4.14	8	Bacteria
Human mitochondria	22	22	0.34	1.1	2	Organelle
<i>Arabidopsis thaliana</i> chloroplast	38	38	0.59	1.9	4	Organelle
<i>Saccharomyces cerevisiae</i>	295	287	4.61	13.67	22	Eukarya
<i>Arabidopsis thaliana</i>	639	630	9.84	31.5	76	Eukarya
<i>Caenorhabditis elegans</i>	820	606	8.47	28.9	55	Eukarya
<i>Drosophila melanogaster</i>	304	299	4.67	14.95	26	Eukarya
Danio rerio	12 844	12 808	200.13	609.9	1583	Eukarya
<i>Xenopus tropicalis</i>	2 586	2 582	40.41	122.95	266	Eukarya
<i>Mus musculus</i>	435	434	6.80	20.67	57	Eukarya
<i>Homo sapiens</i>	625	509	9.77	24.23	43	Eukarya

Note: Total numbers of predicted genes from different genomes are retracted from the Genomic tRNA Database. It is further divided as tRNAs decoding the 20 standard amino acid and selenocysteine, suppressor tRNAs (CTA, TTA), tRNAs with undertermined or unknown isotypes, and pseduogenes. The human mitochondrial tRNA genes were cross-checked with mitoRNAdb and Mamit-tRNA. The plant *Arabidopsis thaliana* chloroplast tRNA genes were retracted from tRNADB-CE.

Genomic analyses have greatly advanced our knowledge on the number of tRNA genes and there are several good resources available to explore this information. The tRNomics project has analyzed more than 4000 sequences of cytosolic tRNAs from 50 genomes (Marck and Grosjean, 2002). The Bayreuth database of tRNAdb system (see Relevant Websites) contains more than 12 000 tRNA genes from 577 species and 623 curated tRNA sequences from 104 species, as well as more than 30 000 mitochondrial tRNA genes from over 1500 metazoan species. The GtRNAdb Genomic tRNA database (see Relevant Websites) contains annotation of 797 genomes from Eukarya (82 taxa), Bacteria (629 taxa), and Archaea (86 taxa) (Chan and Lowe, 2009). Another comprehensive database is tRNADB-CE (see Relevant Websites) that provides annotations of 595,115 tRNA genes from more than 7000 genomes, except Metazoa (Chan and Lowe, 2009). Other information on mitochondrial tRNA (mt-tRNAs) from mammals (see Relevant Websites) and tetrapods is also available from specialized databases (Putz et al., 2007; Popadin et al., 2007).

Analysis by tRNAscan-SE indicates that the reference human genome contains 625 cytoplasmic tRNA genes (Abe et al., 2011). Among these, 446 genes (280 different sequences) are predicted to fold into the canonical cloverleaf structure with zero or at most one mismatch in the stem; 167 genes (160 different sequences) are predicted to have more than one mismatch in the stems (Parisien et al., 2013). Since a mature tRNA contains 74–93 nucleotides, the entire repertoire of human tRNA sequence is made of ~60 000 base pairs representing nearly 0.02% of the genome. Considering that nearly all tRNA genes contain extra sequences that are required to be trimmed off during processing and 32 of them have introns, the total size of tRNA genes in the genome is even more than this number.

The recent 1000-genomes project, which was designed to examine human genetic variation by sequencing a large number of people, demonstrates the great sequence diversity of tRNA genes in the human genome (Parisien et al., 2013). This project also identified new tRNA sequences that are only encoded in a few percent or less of the human population; 76 new tRNA genes exist in >0.2% of all individuals. Interestingly, some tRNA genes encode for tRNAs that could not be aminoacylated, while other genes unexpectedly contained base-pair mismatches in the tRNA structure, suggesting that these genes produced inactive tRNA molecules or tRNAs with new, non-canonical, extra-translation functions. Together this highlights the evolutionary changes occurring in the human population and suggests that these changes in tRNAs may be linked to human complexity (Parisien et al., 2013).

Degenerative tRNAs in Mitochondria

Despite the cloverleaf structure that exists in most tRNAs, tRNAs with atypical cloverleaf structures have been identified. For example, the variation of base pair number in the stem regions of tRNA^{Sec}, tRNA^{Pyl}, and the degenerative sequence in mt-tRNAs.

A major group of tRNAs that deviate from the canonical structure of tRNAs are mitochondrial tRNAs (mt-tRNAs). Mitochondrial genomes encode most of the tRNAs to be used in mitochondrial translation (Kurland, 1992). Due to the evolutionary pressure for minimizing the mitochondrial genome size, many eukaryotes contain only a minimal set of mt-tRNA genes, while in others the set is partial or totally absent from the mitochondrial genome and requires importing missing tRNAs from the cytosol. Large-scale sequencing of mt-genomes has compiled 22 mt-tRNA genes in mammals with

Figure 4 Structure of mitochondrial tRNAs. The mitochondrial tRNAs show divergent structures with atypical (a) or resected (b–d) cloverleaf folds. (a) human (*Hs*) mt-tRNA^{ASP} with atypical D- and T-loops. (b) *Caenorhabditis elegans* (*Ce*) mt-tRNA^{ASP} missing TSL. (c) human mt-tRNA^{Ser} missing DSL. (d) *Walchia hayashii* (*Wh*) mt-tRNA^{Ala} missing both TSL and DSL. Detailed illustration of diverse mt-tRNA structures can be found at Mamit-tRNA (see Relevant Websites section) and was reviewed elsewhere (Giegé *et al.*, 2012).

one per amino acid, two for leucine and serine isoacceptors, respectively. A characteristic feature of mt-tRNAs is the preferential use of light nucleotides (A, U, and C-rich tRNAs) in most Metazoa, especially in Nematoda and Arthropoda (Helm *et al.*, 2000; Klimov and Oconnor, 2009; Yuan *et al.*, 2010). The low GC content is due to the absence of signature motifs (e.g., G₁₈G₁₉ in D-loop) and other variations in D-loop and T-loop that are standard in canonical tRNAs (Figure 4). Particularly, the conserved residues in the D-loop and T-loop in cytosolic tRNAs are often missing in the mt-tRNAs. Some mt-tRNAs even have resected cloverleaf structures, missing the entire DSL or TSL or both. In fact, all mammalian mt-genomes encode a D-armless tRNA^{Ser}, tRNA^{Ser(GCU)}, and a second serine isoacceptor, tRNA^{Ser(UCA)} of atypical size (Putz *et al.*, 2007). Larger deletions of structural domains are popular in nematode mt-tRNAs such as *Caenorhabditis elegans*, including a systematic absence of cloverleaf arm TSL (T-stem loop) or DSL for nearly all tRNAs (Wolstenholme *et al.*, 1987). tRNAs with extremely short length (44–65 nucleotides) lacking either the TSL or DSL or both are also found in Arthropoda mt-genomes. Despite the extensive degeneration in sequence and progressively simplified core domain, all mt-tRNAs nonetheless are expected to fold into a similar canonical tRNA L-shape for functioning in protein synthesis.

This degenerative feature of mt-tRNAs suggests that alternative scaffolds of tRNAs could exist as long as they maintain the basic function of tRNAs. On the other hand, even the degenerative tRNAs still share the same global structural features including the similar overall size, L-shaped 3D structure, anticodon stem loop, acceptor stem, and ~70 Å distance between the anticodon to terminal Adenosine, (for interacting with aminoacyl-tRNA and ribosome). Other molecules that mimic the function of tRNAs also share this global structure, as seen in the case of viral tRNA-like structure (tmRNA), translation termination recycling factor, and other tRNA mimics.

Aminoacyl-tRNA Synthetases

Decoding the genetic code from mRNA to protein includes two steps, attachment of the amino acid to tRNA and the pairing of tRNA with mRNA codon. This decoding is established at the first step of translation by enzymes called aminoacyl-tRNA synthetases, which were discovered by Paul Zamecnik and Mahlon Hoagland in 1957 (Hoagland *et al.*, 1957). Recognition of the codon on mRNA by a particular aminoacyl-tRNA happens at the ribosome. Therefore, the tRNA synthetases occupy a special position in molecular biology and the fidelity of the genetic code.

tRNA Aminoacylation

Aminoacyl-tRNA Synthetase (aaRSs) enzymes are highly conserved proteins that exist in every single cell. There are in general 20 aaRSs that each corresponds to one amino acid (Schimmel and Soll, 1979). The 20 aaRSs are thought to have arisen early in evolution, amongst the first proteins to appear in transition from the primordial RNA world to the theatre of proteins (Woese *et al.*, 2000). They can be divided into two classes, each class containing about 10 members (Figure 5). The Class I aaRSs access the minor groove of tRNA and transfer the amino acid onto the 2' -OH group on the ribose of the terminal adenosine (A76); the Class II aaRSs access the major groove of tRNA and transfer the amino acid onto the 3'-OH on the ribose of A76. The exception is PheRS, which is a Class II enzyme but charges the amino acid to 3'-OH of A76 (Ruff *et al.*, 1991; Eriani *et al.*, 1990). All aaRSs catalyze the reaction in two steps; in the first step, ATP and amino acid bind to the aaRS and the carboxyl group of the amino acid is activated by forming a high energy aminoacyl-AMP (adenosine monophosphate) bond and pyrophosphate (PPi); in the second step, the amino acid carboxyl group is further transferred (charged) to the 2' or 3'-OH group of the ribose at the

Figure 5 Two classes of aminoacyl-tRNA synthetases. (a) The specific ligation of 22 amino acids is carried out by the 21 aminoacyl-tRNA synthetases (including PylRS that is not universally present. tRNA^{Sec} is initially charged by SerRS with Ser, then converted to Sec-tRNA^{Sec}), that equally divided into two classes based on their distinct evolutionary origins. The LysRS contains both class I (α-proteobacteria) and class II (most organisms). (b) Class I aminoacylation domain has a typical Rossmann fold. (c) Class II aminoacylation domain has 7 β-strand sheet fold, which in general bind to the opposite sides of the acceptor stem helix of tRNA.

Figure 6 Recognition of tRNAs by aaRSs. (a) The standard aaRS:tRNA complex recognizes the anticodon loop and acceptor stem end of the cognate tRNA as shown in the *Aquifex aeolicus* MetRS:tRNA^{Met} (pdb2csx) versus (b) the non-anticodon recognition mode of tRNA as shown in the *Thermus thermophilus* SerRS:tRNA^{Ser} (pdb1ser) and (c) in the *Desulfitobacterium hafniense* PylRS:tRNA^{Pyl} (pdb2zni).

terminal 3' end of tRNA (A76) and AMP is released (First, 2005).

Combined: $\text{AA} + \text{ATP} + \text{tRNA} \rightarrow \text{AA-tRNA} + \text{PPi}$ (Harms *et al.*, 2001).

While all aaRSs follow this two-step reaction in a consecutive independent manner, some aaRSs, namely GlnRS,

GluRS, and ArgRS, catalyzes the first step reaction only when the tRNA is bound to the enzyme.

Identify Element of tRNAs

The fidelity of protein synthesis depends on specific tRNA aminoacylation by aminoacyl-tRNA synthetase enzymes. This in turn depends on the recognition of particular nucleotides and structural features in the cognate substrate tRNA. For this reason, each aaRS enzyme is specific for one amino acid and

one or more isoaccepting tRNAs. The general scheme of interaction between aaRS and tRNA is seen in Figure 5. In the complex of *E. coli* tRNA^{Gln} with GlnRS, tRNA^{Gln} is bound to the major groove side of the acceptor stem helix, with its anticodon loop being directly recognized by the anticodon binding domain of GlnRS (Rould *et al.*, 1991). The 3' C₇₄C₇₅A₇₆ end of tRNA^{Gln} turns toward the inside of the catalytic cavity in GlnRS to access the bound L-Gln and ATP. The discriminator base (N₇₃) provides the sharp turn and also makes contact with the catalytic domain of GlnRS. Other interactions also occur at the acceptor stem and the anticodon stem. A similar binding mode was also found in other class I aaRSs, such as MetRS (Figure 6). The complex of yeast tRNA^{Asp} with Class II AspRS occurs in a mirrored pattern, with similar interactions to the anticodon loop, the CCA end and the stems, however, with AspRS bound to the minor groove side of the tRNA^{Asp} acceptor helix (Ruff *et al.*, 1991). This mirrored interaction between Class I and Class II aaRSs with tRNAs prompted the hypothesis that the two classes evolved from a single primordial aaRS gene, or a tRNA chaperon protein, that was transcribed in both direction to produce two 'mirror image' aaRS proteins (Ribas de Pouplana and Schimmel, 2001).

Surprisingly, the identity elements of tRNAs (i.e., the features recognized by the appropriate aaRS, but rejected by inappropriate aaRSs) are not restricted to the anticodon. In some cases the anticodon is completely unrecognized by the aaRSs. These features generally reside within the acceptor helix, the long variable loop, and the anticodon stem-loop of the tRNA.

As an example, a typical recognition of tRNA by aaRSs can be found with aspartic acid tRNA (tRNA^{Asp}) and yeast AspRS. *S. cerevisiae* AspRS was the first synthetase that yielded crystals when complexed with tRNA (Ruff *et al.*, 1991; Giegé *et al.*, 1980). The fidelity of correct aminoacylation on tRNA^{Asp} is insured by a series of interactions that span from the anticodon to the acceptor end of the tRNA. Specifically these are governed by direct base interactions in the anticodon, as well as backbone-mediated interactions within the entire acceptor helix of tRNA^{Asp}. All three bases from the tRNA anticodon are universal aspartate identity determinants of the tRNA^{Asp} and are recognized by AspRS. Anticodon Q34 (in *E. coli*, G34 in yeast) and U35 are the strongest identity determinants (Giegé *et al.*, 1998; Putz *et al.*, 1991), making direct interactions with the N-terminal anticodon binding domain of AspRS and a single mutation affecting the interaction with G34 inactivates the enzyme (Ador *et al.*, 1999). The G73 discriminator base in tRNA^{Asp} serves as another major aspartate identity element, particularly as mutation of this base results in mischarging of the tRNA (Ruff *et al.*, 1991; Putz *et al.*, 1991). Direct proof that G73 is a discriminator base was later demonstrated with the complex structure of yeast AspRS: tRNA^{Asp}. In this structure, both bases with the strongest identity determinant, G73 and C74, are specifically recognized by the active site of AspRS. The 3'-end nucleotide A76 of the CCA-acceptor extremity is also secured in the active site by hydrogen bonding with the 2'-OH of the ribose, placing the ribose in the right position for binding the aspartyl group on O3' (Moulinier *et al.*, 2001). Similar anticodon recognition and discriminator recognition of major identity elements is found in most aaRSs, such as MetRS, GluRS, GlnRS, CysRS,

TrpRS (Class I) as well as LysRS, GlyRS, AsnRS, ProRS, etc. (Class II).

Conversely, other aaRSs recognize the cognate tRNAs based on different identity features in addition to, and sometimes completely independent of, the anticodon and discriminator sequence. For example, HisRS also recognizes the unique G-1 nucleotide at the 5'-end of tRNA, which is only present in histidine tRNAs (Rosen and Musier-Forsyth, 2004; Himeno *et al.*, 1989; Yuan *et al.*, 2011).

In the alanine system, fidelity is ensured by a G•U base pair located at the third position (G3•U70) within the acceptor helix of alanine tRNA (tRNA^{Ala}). Genetic, biochemical and biophysical data suggest that the G•U pair provides a distinctive structure that is directly recognized by the AlaRS to position the tRNA acceptor end into the active site of AlaRS (Gabriel *et al.*, 1996). In fact, AlaRS could aminoacylate an acceptor stem-loop moiety of tRNA^{Ala} (minihelix) that is completely deprived of the anticodon stem-loop (Beuning *et al.*, 2002). Further, introduction of the G₃:U₇₀ base pair into other tRNAs enables efficient aminoacylation by AlaRS (Lovato *et al.*, 2004). Structural analysis of AlaRS:tRNA^{Ala} indicates that AlaRS only interacts with the upper helix of the L-shaped tRNA^{Ala}, the elbow region of D- and T-loops, with no contact to the bottom helix and the anticodon (Sokabe *et al.*, 2009; Naganuma *et al.*, 2009; Guo *et al.*, 2009). AlaRS recognizes the G3•U70 by directly recognizing the base pair from both major and minor grooves, by which it controls the 3'-CCA end to reach the catalytic site in a productive form (Naganuma *et al.*, 2014). These findings spawned the hypothesis that before the formation of the modern genetic code, the primordial tRNA evolved from duplication of a simple helical stem-loop (minihelix) that was promiscuous for amino acid charging (Schimmel *et al.*, 1993).

The evolution of tRNA synthetases reveals that they all contain an ancient catalytic domain positioned at the root of all life followed by the addition of a second domain later in evolution, which in many cases interacts with the anticodon of its cognate tRNA. This suggests that early tRNA recognition was based in large part on nucleotide determinants in the tRNA acceptor stem and this was followed by the development of a system of recognition based on the anticodon loop. This development is considered as a second genetic code (de Duve, 1988). In support of this, the major recognition elements of *Methanococcus jannaschii* tRNA^{Tyr} are the discriminator base A73 and the first C₁•G₇₂ base pair in the acceptor stem, whereas the anticodon triplet participates only weakly in identity determination (Fechter *et al.*, 2001; Steer and Schimmel, 1999). For that reason, the anticodon triplet can be changed without changing the aminoacylation activity of *M. jannaschii* TyrRS (Wang and Schimmel, 1999). For example the anticodon of *M. jannaschii* tRNA^{Tyr} can be converted to the amber suppressor anticodon sequence CUA (or any other anticodon of interest) so that the mutant *M. jannaschii* TyrRS will now insert Tyr during translation of the amber stop codon UAG in mRNA. This finding has led to the beginning of an exciting new field of protein engineering by site-specific incorporation of unnatural amino acid (reviewed elsewhere Xie and Schultz, 2005).

There are other examples of tRNAs that are charged without direct recognition of the anticodon and that include tRNA^{Leu},

tRNA^{Pyl}, tRNA^{Ser} and tRNA^{Sec}. The tRNA^{Ser} adopts a tripod-like structure with a unique long variable hairpin-loop protruding out ($\sim 45^\circ$) from the plane of the L-shaped tRNA (Figure 6). SerRS uses a special two-helical bundle to recognize this variable region as a major determinant, with no interaction between SerRS and the anticodon of tRNA^{Ser} (Biou *et al.*, 1994). This pattern of recognition may be a requisite for SerRS to recognizing multiple tRNA^{Ser} isoacceptor for equal reading of the six serine codons. SerRS is also required for translation of the 7th codon, UGA termination codon on tRNA^{Sec}. The synthesis of tRNA^{Sec} requires it first to be charged with Ser by SerRS and then converted into selenocysteine, the 21st amino acid (Bock *et al.*, 1991). Similarly, tRNA^{Sec} also contains a tripod-like structure with a long variable hairpin recognized by SerRS (Kryukov *et al.*, 2003). This requirement for multiple isoaccepting tRNAs, is in sharp contrast with the previous case of AspRS, where aspartate specificity involves a single tRNA^{Asp}.

The idiosyncratic structure of tRNA^{Pyl} also allows a unique recognition pattern by PylRS. Distinct from all other canonical tRNAs, tRNA^{Pyl} has a compact core structure with re-organized tertiary base pairs (Figure 6). PylRS mainly recognizes tRNA^{Pyl} through this unusual core (Nozawa *et al.*, 2009). From the inner side of the elbow of tRNA^{Pyl}, the C-terminal tRNA binding domain of PylRS makes extensive contacts with the sugar backbones of the D-stem base pairs (G₁₀•C₂₅ to C₁₃:C₂₂), the T ψ C-loop from the minor groove side. It also forms stacking interaction with a 'flipped out' guanine base of G9 in the tRNA^{Pyl}-specific unusual minimal core (Nozawa *et al.*, 2009). PylRS also recognizes the special U-shaped acceptor helix structure of tRNA^{Pyl}. In contrast, the anticodon arm of tRNA^{Pyl} does not make any specific contacts with PylRS. Structural analysis suggests that PylRS is probably one of the earliest evolved aaRSs among the total 21 aaRSs (Kavran *et al.*, 2007) and in this and other cases the anticodon does not participate in amino acid identity, such as AlaRS. The exceptional recognitions for these aaRSs are found throughout all three kingdoms of life, further suggesting the essential role

of aaRSs in establishing the genetic code in the initial step of evolution.

Proofreading of Aminoacyl-tRNAs

The similarity of some amino acids can result in the mischarging of tRNAs and these errors are corrected by either reversal of the charging or by modifying the amino acid to the correct form. The earliest hint of mischarging of tRNA by non-cognate amino acid came from the fact that, although there are 20 standard amino acids, many organisms do not possess all 20 aaRSs. This was first observed for *Bacillus subtilis* when it was shown that Gln-tRNA^{Gln} is formed via the transfer of an amino group onto Glu-tRNA^{Gln} (Kunst *et al.*, 1997; Curnow *et al.*, 1997b). Later, it was demonstrated that both tRNA^{Glu} and tRNA^{Gln} are charged with glutamate by a single GluRS. The amidotransferase that subsequently converts Glu-tRNA^{Gln} to Gln-tRNA^{Gln} has been characterized and shown to co-bind with tRNA^{Gln} together with the non-discriminating GluRS thus preventing leaking of the intermediate Glu-tRNA^{Gln} to translation (Curnow *et al.*, 1998; Curnow *et al.*, 1997a). A similar situation was later found in gram-positive eubacteria, archaea, chloroplasts, as well as mitochondria. A similar misacylation-transamidation pathway to produce Asn-tRNA^{Asn} was also found in the halophilic archaea (Min *et al.*, 2002; Kim *et al.*, 1996). In these examples a system has evolved to make use of the mischarging by GluRS and AspRS eliminating the need for the GlnRS and AsnRS genes.

The correct recognition of amino acids by modern aaRSs is essential for the accuracy of translation and uncorrected mischarging events will result in mistranslation leading to corruption of the proteome. However, the differences between similar amino acids are not large enough for the enzymes to rigorously discriminate (Pauling, 1958). To achieve higher discrimination, amino acid recognition is split into two-steps that involve a partially accurate synthetic step followed by a proofreading or editing step that eliminates misactivated

Figure 7 Pre-transfer and post-transfer editing of mischarged aa-tRNAs. A cognate amino acid (blue) is activated at the aminoacyl-tRNA synthetase (aaRS) active site with ATP to form an aminoacyl adenylate (1), releasing pyrophosphate (PPi). Subsequently, a cognate tRNA binds to the aaRS, and the amino acid is attached to the 3' end of the tRNA and AMP is released, forming an aminoacyl-tRNA (2). The non-cognate amino acid could be either removed before transferring to tRNA (3) or after (4). The aminoacyl-tRNA is then released and binds to elongation factor Tu (EF-Tu). In some cases, the EF-Tu bound aminoacyl-tRNAs could also be further checked by recycling back to the empty aaRS (5). The proofreading by free-standing editing enzymes may also happen at this recycling circle. Final aminoacyl-tRNA that passes the quality control steps will be delivered to ribosome for protein synthesis.

noncognate amino acids. There are two checkpoints to monitor the fidelity of amino acid/tRNA charging (Figure 7); (1) After the AMP activation of amino acids (AA-AMP, pre-transfer, reaction (3)); (2) After the charging of tRNA (AA-tRNA, post-transfer, reaction (4)). The mis-activated aminoacyl-AMPs are cleared at the synthetic site – pre-editing; or the mischarged tRNAs are cleared by hydrolytic editing (Fersht, 1977; Jakubowski and Goldman, 1992; Ibba and Soll, 1999; Ling *et al.*, 2009), at a second, discrete active site within an editing domain – post-editing (Sokabe *et al.*, 2009; Cusack *et al.*, 2000; Fukai *et al.*, 2000; Ahel *et al.*, 2003; Wong *et al.*, 2003; An and Musier-Forsyth, 2004; Fukunaga and Yokoyama, 2005; Sokabe *et al.*, 2005). For example, IleRS is not able to discriminate between isoleucine and valine; however, valine-tRNA^{Ile} can be recognized by the editing domains and hydrolyzed (reaction (3)).

These editing domains have been identified for the class I IleRS, ValRS, and LeuRS and for the class II AlaRS, ThrRS, PheRS, and ProRS (Sokabe *et al.*, 2009; Naganuma *et al.*, 2009; Cusack *et al.*, 2000; Fukai *et al.*, 2000; Ahel *et al.*, 2003; Wong *et al.*, 2003; An and Musier-Forsyth, 2004; Fukunaga and Yokoyama, 2005a,b,c; Sokabe *et al.*, 2005; Tukalo *et al.*, 2005; Crepin *et al.*, 2006; Hussain *et al.*, 2006). Early structures of ValRS/IleRS/LeuRS re-capitulated the double-sieve (two active sites) model proposed by Fersht for the three close-related class I aaRSs (Fukai *et al.*, 2000). If the wrong amino acid becomes attached to a tRNA, the bound synthetase catalyzes removal of the amino acid from the tRNA, through a separated editing domain that specifically recognizes the mis-linked amino acid (CP1 domain). This process requires the flip-over of the 3' CCA end of the tRNA to present its linked amino acyl-group to the editing domain, and is called post-editing reaction. After dissociating from aaRSs, the aminoacyl-tRNA will be bound by elongation factor and delivered to ribosome for translation.

In addition to the immediate editing steps at the aaRS, the released AA-tRNAs that have already been bound by elongation factor will also sometimes recycle back to the tRNA

synthetase for a third check and hydrolysis if it is inappropriate. One example shown for the *E. coli* PheRS was discovered in *in vitro* translation system, where mischarged Tyr-tRNA^{Phe} could be dissociated from the elongation factor EF-Tu and rebound to the PheRS. PheRS will then double check the mischarged Tyr-tRNA^{Phe} and hydrolyzes it through its editing domain (Ling *et al.*, 2009). Although elongation factor EF-Tu, shows some preference for correctly charged AA-tRNAs, it binds efficiently to mischarged AA-tRNAs as well. This can be exemplified by the extreme cases where hundreds of different non-natural amino acids have been successfully incorporated into protein by engineering the specificity of tRNA synthetases (Xie and Schultz, 2005; Malyshev *et al.*, 2014; Wang *et al.*, 2007). Thus the elongation factors are not major contributors to editing of mischarged tRNAs.

Finally in addition to editing by the synthetases, there is a separate set of free-standing editing enzymes that bind and hydrolyze mischarged tRNAs that leak from the aaRS. These enzymes show homology to the editing domains of tRNA synthetases and as examples include AlaXp (AlaXp-I, -II, -III, for tRNA^{Ala}), ThrX (for tRNA^{Thr}), ProX and Ybak (for tRNA^{Pro}) (Fukunaga and Yokoyama, 2007; Chong *et al.*, 2008; Ruan and Soll, 2005; Murayama *et al.*, 2005). They are widely present in multiple species throughout the three kingdoms of life (Guo *et al.*, 2009; Ahel *et al.*, 2003; Ruan and Soll, 2005; Korencic *et al.*, 2004) and provide yet another layer for proofreading and removal of mischarged tRNAs.

In all, these proofreading mechanisms highlight the importance of high fidelity in translating the genetic code and the essential role that the tRNA synthetases, by supplying the correct AA-tRNA for peptidyl formation, play in this fundamental process.

tRNA in Translation

Translation of mRNA occurs at ribosomes where two different ribosomal subunits assemble on mRNA, a small subunit (30S in prokaryotes and 40S in eukaryotes) and a large subunit (50S in prokaryote or 60S in eukaryote). A typical eukaryotic cell contains millions of ribosomes in its cytoplasm (Farrell, 2010). The complete ribosome contains a binding site for

Figure 8 Three tRNAs bound in ribosome for protein translation. (a) Each ribosome has one binding site for mRNA and three binding sites for tRNA: the A-, P-, and E-sites (short for aminoacyl-tRNA, peptidyl-tRNA, and exit, respectively). (b) Each amino acid added to the growing end of a polypeptide chain is selected by complementary base-pairing between the anticodon on its attached tRNA molecule and the next codon on the mRNA chain. Because only one of the many types of tRNA molecules in a cell can base-pair with each codon, the codon determines the specific amino acid to be added to the growing polypeptide chain.

mRNA and three binding sites for tRNA called the A-site, P-site, and the E-site (**Figure 8**).

A-Site (Aminoacyl Site): It is the site where aminoacyl-tRNA enters ribosome. The anticodon of the specific AA charged tRNA base pairs with the codon on mRNA providing the selectivity for decoding the mRNA.

P-Site (Peptidyl Site): It is the site where the peptidyl tRNA is formed in the ribosome. The amino acid is transferred from the tRNA in A-site.

E-Site (Exit Site): It is the site where tRNA moves to after transfer of the amino acid in the P-site and before leaving the ribosome. The designs and functions of eukaryotic, archaeal and bacterial ribosomes are similar ([Ramakrishnan, 2002](#); [Harms et al., 2001](#)).

The translation can be divided into three stages: initiation, elongation and termination, where tRNAs are re-located from A site to P site and E site accordingly. High resolution structures

of ribosome obtained from X-ray crystallography and Cryo-EM confirmed that tRNA keeps the L-shaped conformation in all three sites, with considerable conformational changes to promote translation at each step ([Fernandez et al., 2014](#); [Amunts et al., 2014](#); [Tourigny et al., 2013](#); [Schmeing and Ramakrishnan, 2009](#); [Gao et al., 2009](#); [Weixlbaumer et al., 2008](#); [Selmer et al., 2006](#); [Valle et al., 2003](#); [Brodersen et al., 2000](#); [Wimberly et al., 2000](#); [Lomakin and Steitz, 2013](#); [Polikanov et al., 2012](#); [Blaha et al., 2009](#); [Ban et al., 2000](#)).

tRNA in Translation Initiation

Translation is a complex enzymatic process that requires ribosome, mRNAs, tRNAs, and multiple protein translation factors. In prokaryotes, three initiation factors (IF1, IF2 and IF3) are responsible for the initiation of translation ([Dever, 2002](#)). In eukaryotes, initiation involves more than 12 protein

Figure 9 tRNA in translation initiation complex. Three initiation factors (IF1, IF2, and IF3) first bind to the 30S ribosomal subunit in bacteria. This step is followed by binding of the mRNA and the initiator *N*-formyl-methionyl (fMet) tRNA^{fMet}, which is recognized by IF2 bound to GTP. IF3 is then released, and a 50S subunit binds to the complex, triggering the hydrolysis of bound GTP, followed by the release of IF1 and IF2 bound to GDP.

factors including EIF1, eIF1A, eIF2, eIF2B, eIF3, eIF4A, eIF4E, eIF4G, eIF5, and eIF5B, where many of them play important regulatory roles during this step (Kozak, 2005; Allen and Frank, 2007; Hinnebusch and Lorsch, 2012).

Translation Initiation consists of three steps. First, mRNA is bound to the ribosome small subunit. Second, the initiator tRNA will recognize and bind to the mRNA initiation AUG codon, through a codon–anticodon match. Third, the large subunit is recruited to this initiation complex and proceeds to protein synthesis (Ramakrishnan, 2002; Wilson and Hunt, 2008).

Protein synthesis in general starts with an AUG codon near the beginning of the mRNA, following the 5'-UTR, which often contains regulator elements for translation control. To distinguish the initiation codon from internal methionine codons, prokaryotes contain a specific sequence, Shine–Dalgarno sequence (UAAGGAGG), which is located about 5–10

nucleotides before the initiation codon. Close to the 3' end of 16S RNA of 30S ribosomal subunit, there is a nucleotide sequence complementary to Shine–Dalgarno sequence. The interaction of these two sequences accelerates the binding of mRNA to the 30S ribosomal subunit (Figure 9). In eukaryotes, the first AUG codon is recognized by a specific initiation tRNA. A distinction between bacteria and eukaryotes also exists in this initiation tRNA. In prokaryotes, proteins synthesis is initiated with *N*-formyl methionyl tRNA^{fMet}. In eukaryotes, protein synthesis is initiated with non-formylated, but a special methionyl initiator tRNA (tRNA^{iMet}) (Varshney *et al.*, 1993; Myasnikov *et al.*, 2009). During initiation, IF3 binds to the 30S ribosome small subunit and prevents the binding of large subunit. Bacterial initiation complex includes initiation factor (IFs), GTP, ribosome subunits, mRNA and fMet-tRNA^{fMet} (Ramakrishnan, 2002; Varshney *et al.*, 1993; Myasnikov *et al.*, 2009).

Figure 10 tRNA in translation elongation complex. A cognate aminoacyl-tRNA bound to EF-Tu binds to its cognate codon of the mRNA in the ribosome at the acceptor site (A site), adjacent to the tRNA in the peptidyl site (P site), which is bound to the nascent polypeptide (1). Decoding occurs on the 30S subunit of the ribosome, GTP is hydrolysed by EF-Tu, which leads to release of aminoacyl-tRNA into the A site if there is correct codon–anticodon pairing. Subsequent peptide bond formation between the nascent polypeptide in the P site and the amino acid attached to the tRNA in the A site results in a peptidyl-tRNA in the A site that is one amino acid longer (2). After translocation of the ribosome, the tRNA attached to the nascent polypeptide is moved to the P site and a new aminoacyl-tRNA is delivered to the empty A site (3).

The second step of initiation involves the binding of initiator fMet-tRNA^{fMet} to the initiation codon. In this step, IF2 plays a key role by controlling entry of tRNA into the P site of ribosome. IF2 in GTP-bound form is directly bound to the P site in 30S subunit. Then fMet-tRNA^{fMet} binds to IF2 and IF2 transfers fMet-tRNA to the P site. IF1 remains associated with the 30S ribosomal subunit in A site and maintains the separation of small and large subunits, further preventing entry of other aminoacyl-tRNAs to the A site.

At the final step of initiation, the 50S large subunit is joined to the 30S small subunit. Energy required for the initiation step is provided from the hydrolysis of guanosine triphosphate (GTP) by IF1 and IF2. IF2 is released and the initiation complex of protein synthesis is formed. The resulting initiation complex is a 70S ribosome with an empty A site, carrying initiator fMet-tRNA^{fMet} in P site bound to mRNA (Schmeing *et al.*, 2009). Eukaryotic translation initiation is similar to that of bacteria but more complex. In addition to the different initiator tRNA^{iMet}, eukaryotic initiation complex is also associated with the 3' poly(A) tail of mRNA, the 5'-cap structure (5' end of eukaryotic mRNAs), the Kozak sequence in mRNA that increases the efficiency of initiator tRNA entering the ribosome, and more eukaryotic specific inhibition factors (eIFs) (Polikanov *et al.*, 2012; Ban *et al.*, 2000).

tRNA in Elongation

In the elongation step, amino acids are combined to form a polypeptide chain in the ribosome. It includes all reactions from the first peptide bond formation to the last peptide bond formation in the synthesis of a single protein (Ramakrishnan, 2002; Alberts, 2008).

After initiation the ribosome is bound to mRNA with the AUG initiation codon positioned by fMet-tRNA^{fMet} at P site while the A site is empty (Schmeing *et al.*, 2009). Prokaryotic translation elongation involves this initiation complex as well as tRNAs charged with their cognate amino acids (aminoacyl-tRNAs), elongation factors EF-Ts (elongation factor thermo stable), EF-Tu (elongation factor thermo unstable) and EF-G (historically known as translocase) and GTP (Ramakrishnan, 2002; Tourigny *et al.*, 2013; Schmeing and Ramakrishnan, 2009; Selmer *et al.*, 2006).

Elongation occurs in three steps (Ramakrishnan, 2002; Frank and Gonzalez, 2010; Figure 10). The first step is the binding of aminoacyl-tRNAs matching the codon in the mRNA at the ribosome A site. Aminoacyl-tRNAs (AA-tRNAs) generated by the aminoacyl-tRNA synthetases are prone to hydrolysis in water. To deliver aminoacyl-tRNA to ribosomes efficiently, a GTP-bound EF-Tu will bind specifically to the charged tRNAs and protect amino acid (AA) from hydrolysis as well as masks it from peptide bond formation. After formation of the initiation complex, thanks to hydrolysis of GTP and elongation factor (EF-Tu) at the A site of this complex, aminoacylation-tRNA uses the anticodon to recognize the codon sequence on mRNA. The EF-Tu•GTP:AA-tRNA ternary complex enters the ribosome A site by matching the anticodon of tRNA to the codon on mRNA. EF-Tu then interacts with a factor binding site in the ribosome large subunit that triggers its GTPase activity. GTP hydrolysis results in the separation of the complex into EF-Tu•GDP and phosphate (Pi) and

aminoacyl-tRNA is released (Ramakrishnan, 2002; Schmeing and Ramakrishnan, 2009; Schmeing *et al.*, 2009; Frank and Gonzalez, 2010).

The crystal structure of ribosome associated with the ternary complex EF-Tu•GTP:AA-tRNA revealed a strongly distorted structure of tRNA bound at the A site. With the anticodon binding to the codon on mRNA, the interaction leads to a ~30° bend of the anticodon (AC)-stem and a 5 Å swing of the D-stem moving away from the T-stem. This distortion allows the AA-tRNA to interact simultaneously with elongation factor and cognate codon in the decoding center of 30S subunit. The relaxation of the bent conformation may accompany the hydrolysis of GTP to promote tRNA translation from the A to P site (Ramakrishnan, 2002; Tourigny *et al.*, 2013; Schmeing and Ramakrishnan, 2009; Selmer *et al.*, 2006).

EF-Tu•GDP is inactive and must be activated before the next elongation cycle. For this, EF-Ts is required, because affinity of EF-Tu for GDP is 40 times greater than its affinity for GTP. EF-Ts activates EF-Tu exchanging GDP with GTP. EF-Tu does not interact with fMet-tRNA^{fMet} because initiator fMet-tRNA^{fMet} never enters the A site (Ramakrishnan, 2002; Alberts, 2008).

The second step in elongation involves the transfer of the initial methionine or peptide from the tRNA in the P site to the amino acid attached to tRNA in the A site. This occurs through the hydrolysis of the ester bond between the amino acid and the 3' -OH group of tRNA in the P site and the formation of a peptide bond with the amino acid -NH₂ group in the A site tRNA. The reaction breaks the bond between tRNA in the P site and the initial methionine or peptide, and then transfers the methionine or peptide onto the amino acid bound to the tRNA in the A site. This reaction is called peptidyl transferase reaction, with the responsible region in the ribosome is called peptidyl transferase center (Figure 10).

Translocation is the third step of the elongation phase and involves positioning of the ribosome to read the next codon and requires GTP hydrolysis of elongation factor G (EF-G). The hydrolysis of GTP to GDP alters the three dimensional structure of EF-G. This alteration of EF-G moves the peptide-tRNA in the A site to the P site. Because this peptide-tRNA is base paired with the mRNA, the mRNA also shifts, positioning the next codon in the empty A site. At the same time, the original tRNA in the P site, now relieved of methionine or peptide, moves to the E (exit) site breaking the base pairing with mRNA. The uncharged tRNA is released from the E site and EF-G•GDP is released from the ribosome (Ramakrishnan, 2002; Schmeing and Ramakrishnan, 2009; Alberts, 2008).

Elongation and translocation reactions in eukaryotes are very similar to those in prokaryotes with minor differences in

Figure 11 tRNA in translation termination complex. When a stop codon (UAG, UAA, or UGA) arrives at the A site, it is recognized and bound by a ribosomal recycling factor. This causes the polypeptide to be transferred to a molecule of water and the release of the polypeptide from the tRNA, followed by the dissociation of the other components of the elongation complex.

proteins. Instead of elongation factors EF-Tu and EF-Ts there is a stable ternary complex made up of eEF1- α - β and γ . eEF1- α is the eukaryotic equivalent of EF-Tu; eEF1- β - γ are eukaryotic equivalents of EF-Ts. eEF2 (eukaryotic elongation factor 2) is the equivalent of prokaryotic EF-G and regulates ribosome translocation. Phosphorylation of eEF2 by EF2 kinase regulates translation elongation by completely inactivating the eEF2-dependent ribosomal translocation (Hershey *et al.*, 2012; Dever and Green, 2012).

tRNA in Termination

Termination phase is the release of the completed polypeptide from the ribosome and occurs when the ribosome arrives at one of the three termination codons (UAA, UAG, and UGA) to the A site. Because there are no complementary tRNAs for the termination codons, no tRNA binds to the A site. Instead, proteins called release factors (RFs) or ribosomal recycling factors (RRFs) recognize the termination codons and terminate translation (Schmeing and Ramakrishnan, 2009; Weixlbaumer *et al.*, 2008; Alberts, 2008).

Ribosomal releasing factors are divided into two classes, Class 1 RRFs and Class 2 RRFs. In prokaryotes, there are two

types of Class 1 RRFs: RF1 and RF2. In eukaryotes, Class 1 RRF has only one; eRF1. In prokaryotes and eukaryotes there is only one Class II factor: RF3 and eRF3, respectively (Nakamura and Ito, 2003; Carraro *et al.*, 2010).

In prokaryotes RF1 is responsible for the recognition of termination codons UAA and UAG and RF2 triggers polypeptide hydrolysis from tRNA in the P site. RF1 and RF2 are similar in size and shape to tRNA and interact with the A site of the ribosome as tRNA does (Nakamura and Ito, 2003). RF3 is structurally similar to EF-G complex and hydrolysis of RF3•GTP to RF3. GDP promotes the separation of the polypeptide chain from the linked tRNA 3'-OH in P site and the release of the polypeptide chain from the ribosome (Figure 11).

The termination of protein synthesis in eukaryotic cells is similar to that in prokaryotes. However, two different releasing factors have been identified. The first one, eRF1, recognizes all three termination codon and is equivalent to RF1 and RF2 in prokaryotes. eRF3 binds with GTP and stimulates the separation of the polypeptide chain from tRNA, similar to RF3 in prokaryotes. Termination by the release factors enable the protein synthesis cycle to end and the mRNA to be translated again or degraded (Dever and Green, 2012; Nirenberg and Tampe, 2013).

Ribosome Recycling

After the release of the polypeptide chain and RRFs, the ribosome (in its P and E site) is still connected to mRNA and uncharged tRNA. For the ribosome to enter a new cycle of polypeptide synthesis, it needs to release the mRNA and tRNA and separate the large and small subunits of the ribosome. EF-G and IF3 help to activate this process and are necessary for ribosome recycling after the release of polypeptide (Franckenberg *et al.*, 2012).

Surprising Number of Roles of tRNAs beyond Translation

Molecular biologists first encountered tRNAs as a key component of the translation machinery and because of this history it is all too easy to think of translation as the primary or proper function of tRNA. But in fact, tRNA and tRNA processing enzymes impact much more than protein production. Studies have uncovered roles for tRNA in the regulation of transcription, translation and protein turnover. Induced by stress or as part of a developmental program, non-random tRNA fragments can guide mRNA cleavage, inhibit translation and promote morphological changes. Similarly, tRNA processing enzymes, such as RNaseP and aminoacyl-tRNA synthetases participate in tasks affecting more than tRNA function (i.e., mRNA function and cellular signaling). Unraveling the complexities of all these functions will increase our understanding of the downstream consequences of mutations in these genes and how they impact health and disease. As we will discuss in detail, tRNA and tRNA-like molecules also play key roles in a wide variety of cellular processes including cell wall and membrane biosynthesis (Shepherd and Ibba, 2013;

Figure 12 GCN2 and tRNA. Amino acid starvation causes the accumulation of uncharged tRNAs that bind to the histidyl-tRNA synthetase (HisRS)-related domain of GCN2 and activate the adjacent protein kinase domain (KD). GCN2 also contains a pseudo-protein kinase domain (ΨKD) of unknown function and an *N*-terminal binding site (N) for the GCN1/GCN20 complex that is essential for recognition of the starvation signal. GCN2 phosphorylates the translation factor eIF2 α , preventing it to be recycled by its guanine nucleotide exchange factor eIF2B and leading to inhibition of protein synthesis. At the same time, phosphorylation of eIF2 α also leads to the translational induction of GCN4 synthesis in yeast and, ATF4 in animals. GCN4 activates the transcription of genes necessary for amino acid biosynthesis. In mice, activation of GCN2 in the brain mediates an aversive response toward intake of diets lacking essential amino acids.

Francklyn and Minajigi, 2010; Dare and Ibba, 2012), antibiotics synthesis (Francklyn and Minajigi, 2010; Banerjee *et al.*, 2010), metabolic regulation (Castilho *et al.*, 2014; Murguia and Serrano, 2012), protein degradation (Mogk *et al.*, 2007), and replication of RNA or DNA from viruses (Saadatmand and Kleiman, 2012; Klasse, 2012; Dreher, 2009; Gomez *et al.*, 2004; Hurto, 2011), etc.

tRNA and GCN2 Pathway

Eukaryotes from yeast to animals select foods to achieve a balanced diet that includes adequate levels of the essential amino acids. When starved for any of several amino acids, yeast cells induce the transcription of over 70 genes encoding enzymes that function in the biosynthesis of all 20 amino acids (Hinnebusch and Natarajan, 2002). Mammals are not capable of synthesizing all 20 amino acids and must obtain essential amino acids from the diet. The presence of essential amino acids is somehow detected and a diet missing any of these amino acids will be rejected by rats. The molecular mechanisms governing this universal 'feeding' behavior is through the accumulation of uncharged tRNAs.

Genetic studies in yeast identified the 'general CONTROL Nonderepressing 2 protein kinase (GCN2)' as the primary sensor of amino acid starvation and the domain structure of GCN2 helps to explain this assignment. In addition to a typical eukaryotic protein kinase domain, GCN2 contains a domain related to histidyl-tRNA synthetase (HisRS), which binds uncharged tRNAs with higher affinity than the corresponding charged tRNAs (Dong *et al.*, 2000). Amino acid starvation results in the accumulation of uncharged tRNAs that bind to the synthetase-like domain of GCN2 and activates the kinase domain (Wek *et al.*, 1995; Figure 12). Active GCN2 phosphorylates the alpha subunit of eukaryotic initiation factor 2 (p-eIF2 α) on serine 51, which inactivates eIF2 α /b/g

and inhibits translation initiation. eIF2 α /b/g bound to GTP delivers the initiator methionyl-tRNA (Met-tRNA^{Met}) to the small ribosomal subunit in the first step of translation. eIF2 α /b/g-GDP is released from the ribosome and is recycled to eIF2 α /b/g-GTP by its guanine exchange factor (GEF) eIF2B, however p-eIF2 α blocks this recycling reaction thereby preventing translation initiation.

Paradoxically, phosphorylation of eIF2 α leads to the translational induction of GCN4 synthesis in yeast, and GCN4 activates the transcription of genes necessary for amino acid biosynthesis. In mice, activation of GCN2 in the anterior piriform cortex of the brain mediates an aversive response toward intake of diets lacking an essential amino acid. Subsequent cellular adaptation to amino acid deprivation is marked by decreases in global protein synthesis complemented by increased transcription of genes related to amino acid biosynthesis (Castilho *et al.*, 2014; Murguia and Serrano, 2012). The components of the pathway linking eIF2 α phosphorylation and downstream behaviors in animals involve the transcription factor ATF4 (Carraro *et al.*, 2010; Harding *et al.*, 2000; Sikalidis *et al.*, 2014), although the complete mechanism remains unknown (Peng *et al.*, 2012).

GCN2 binds and is activated by many different uncharged tRNAs (Dong *et al.*, 2000). A genome-wide analysis of tRNA activation of GCN2 in yeast has shown that GCN2 was activated by multiple uncharged tRNAs during amino acid starvation and, interestingly, these uncharged tRNAs are not necessarily the tRNAs for the missing amino acids. Other environmental stresses such as high salt could also lead to selective deacylation of tRNAs and activation of GCN2. Nonetheless, inhibition of aminoacyl-tRNA synthetases is absolutely responsible for the accumulation of uncharged tRNA. Mutation of an aminoacyl-tRNA synthetase triggers GCN2 activation even in medium replete with amino acids (Hinnebusch and Natarajan, 2002; Dong *et al.*, 2000).

Figure 13 Nontranslational function of tRNAs. In addition to the canonical function of tRNA as substrate for translation, tRNAs have been exploited for various roles in cellular processes, including metabolic regulation, proteolysis, bio-synthesis, replication of telomere and even viral RNA and DNA.

tRNAs for Regulated Proteolysis

The *N*-end rule states that the half-life of a protein is determined by the nature of its *N*-terminal residue. Although prokaryotes and eukaryotes employ distinct proteolytic machineries for degradation of *N*-end rule substrates, recent findings indicate that they share common principles of substrate modification (Mogk *et al.*, 2007).

There are three ways of generating specific *N*-terminal residue that target proteins for degradation; *N*-ter or endopeptidase cleavage, and transfer of amino acids onto *N*-termini (Tasaki *et al.*, 2012). In addition to the methionine aminopeptidase (in *E. coli*) and endopeptidase (in eukaryotes), both *E. coli* and eukaryotes can transfer amino acids from aminoacyl-tRNAs (AA-tRNAs) to certain *N*-termini using enzymatic transferases (Figure 13). This fundamental principle of regulated proteolysis is conserved from bacteria to mammals. For example in eukaryotes, Arg is conjugated to specific proteins by the ATE1-encoded arginyl-tRNA protein transferase (R-transferase), which targets the protein for Ub-dependent degradation (Balzi *et al.*, 1990; Rai and Kashina, 2005). The human pathogen *Vibrio vulnificus* encodes a second L-transferase (Bpt) that is homologous to eukaryotic ATE1. In *E. coli*, Arg and Lys function as secondary destabilizing residues that recruit primary destabilizing residues (Phe, Leu), which are transferred using a leucyl/phenylalanyl-tRNA protein transferase (L/F-transferase or Aat) (Ninnis *et al.*, 2009). The crystal structure of *E. coli* L/F-transferase suggests that the enzyme has preference for different aminoacyl-tRNAs with specific amino acids binding pockets (Watanabe *et al.*, 2007).

tRNAs for Cell Wall Synthesis

In the bacterial cell wall, amino acid modification of peptidoglycan facilitates cross-linkage with the plasma membrane resulting in decreased membrane permeability that is often a prerequisite for high-level antibiotic resistance. Many clinically relevant bacteria, including *Streptococcus pneumoniae*, *Staphylococcus aureus*, *Enterococcus faecalis*, and *Pseudomonas aeruginosa* recruit specific aminoacylated-tRNAs into peptidoglycan

biosynthesis and membrane phospholipid modification (Francklyn and Minajigi, 2010; Dare and Ibba, 2012; Banerjee *et al.*, 2010). The cross-linking of short intra-strand peptides provides the cell with additional rigidity allowing for resistance of *S. aureus* to β -lactam antibiotics, including methicillin (Biarrotte-Sorin *et al.*, 2004). These amino acids, usually Gly and Ala, are transferred from the aminoacyl-tRNA (AA-tRNA) to a hexapeptide lipid intermediate by a series of enzymes, such as FemA/B/X. Each of the Fem proteins attaches several amino acids to build the inter-peptide bridge in a sequential manner (Biarrotte-Sorin *et al.*, 2004; Benson *et al.*, 2002).

In order to participate in peptidoglycan biosynthesis, the AA-tRNAs must escape the cytoplasmic protein translation circuit. Some tRNAs are specially optimized for escaping translation by lacking certain GT ψ C and GG sequence in the acceptor stem loop and are thus unable bind with EF-Tu•GTP and ribosome. Further, the FemX proteins specifically recognize the amino acid moiety (Gly and Ala), the discriminator base of tRNA^{Gly}, and the acceptor stem of tRNA^{Ala}, to recruit these tRNAs for peptidoglycan biosynthesis. Other amino acids, including Ser, Thr, Lys and Arg and their tRNAs are also used for peptidoglycan cross-linking or cell membrane lipid modification (Dare and Ibba, 2012).

In Streptomycetes, aminoacylated tRNAs are also used for antibiotic synthesis as well as antibiotic resistance. The antibiotic valanimycin produced by *Streptomyces viridifaciens* is derived from Val (L-valine) and Ser (L-serine). Val is first transformed into isobutylhydroxylamine that must be reacted with Ser during valanimycin biosynthesis (Garg *et al.*, 2008). A seryl-tRNA synthetase gene unexpectedly identified in the valanimycin biosynthetic gene cluster (vlm) indicates that the seryl residue could be transferred from seryl-tRNA to the hydroxyl group of isobutylhydroxylamine (Garg *et al.*, 2006). Another example of tRNA-dependent antibiotic synthesis is in the biosynthesis of albonoursin (alb) in *Streptomyces noursei* (Gondry *et al.*, 2009). Albonoursin is a cyclodeptide antibiotic made from Phe and Leu by the AlbC enzyme and it was found that charged *E. coli* tRNA^{Phe} and tRNA^{Leu} were the required substrates. The following studies detected numerous other cyclodeptides containing Ala, Val, and Met from the cell extract,

Figure 14 Mechanism of the LysRS/tRNA^{Lys}/Gag/Pol packaging complex in HIV-1. Reverse transcription of the HIV genome is primed by a human lysine-specific tRNA (tRNA^{Lys3}) that is packaged (into the virion) by the HIV Gag protein with simultaneous packaging of tRNA^{Lys3}, LysRS, and Gag. A model here showing Gag, tRNA^{Lys}, and LysRS form a ternary complex. The model suggests that tRNA^{Lys} is mainly anchored through the interaction of the anticodon stem-loop with the anticodon-binding domain, with minimal interaction being seen with the catalytic domain of the synthetase. Other interactions between tRNA^{Lys3} with Gag-Pol may further stabilize the ternary complex for tRNA^{Lys3} incorporation into the HIV virion.

indicating that AlbC and its homologs could use other tRNAs as substrates besides tRNA^{Phe} and tRNA^{Leu}. These examples suggest that tRNAs have many other roles that remain to be uncovered.

tRNAs for Virus Reverse Transcription Initiation

During the replication of RNA viruses, the viral RNA genome is converted into double-stranded proviral DNA by reverse transcription. Initiation of reverse transcription is primed by a cellular tRNA, which is selectively incorporated into the virus during assembly in the cell of origin. The primer tRNA is annealed to an 18-base sequence near the 5' end of the viral RNA genome termed the primer binding site (PBS), and is used to prime the reverse transcriptase-catalyzed synthesis of minus strand cDNA in the newly infected cell.

Different viruses use different cellular tRNAs as primer (Mak and Kleiman, 1997). In lentiviruses, such as human immunodeficiency virus 1 (HIV-1) and mouse mammary tumor virus, tRNA^{Lys3} serves as the primer tRNA (Marquet *et al.*, 1995). However, in avian retroviruses, tRNA^{Trp} is the primer for all members of the avian sarcoma and leukosis virus group examined to date (Swanstrom and Wills, 1997; Morris and Leis, 1999), whereas tRNA^{Pro} is the common primer for murine

leukemia virus (MuLV) (Peters and Hu, 1980). tRNA^{Lys1,2}, two other tRNA^{Lys} isoacceptors differing by one base pair in the anticodon stem (differ from tRNA^{Lys3} by 14 or 16 bases), is also the primer tRNA for several retroviruses, including Mason-Pfizer monkey virus (MPMV) and human foamy virus (HFV).

Primer tRNA is present in the mature virus capsid core prior to initiation of reverse transcription, which may happen before capsid disassembly (Mak and Kleiman, 1997; Kleiman, 2002). Thus, during virus assembly, viral genomic RNA and cellular tRNA isoacceptors (such as tRNA^{Lys3} and tRNA^{Lys1,2}) are selectively concentrated at the site of assembly, and packaged by virus proteins. The packaging complex in HIV-1 includes the capsid Gag protein, reverse transcriptase Pol, and the host human lysyl-tRNA synthetase (LysRS; Figure 14). Both LysRS and Pol interact with tRNA^{Lys} and additional contacts between the viral RNA and LysRS may also occur (Saadatmand and Kleiman, 2012; Guo *et al.*, 2005; Kovaleski *et al.*, 2006; Kovaleski *et al.*, 2007; Kleiman *et al.*, 2010). In HIV-1, estimates of approximately 20 molecules of tRNA^{Lys}/virion have been reported, with about 8 molecules tRNA^{Lys3} and 12 molecules tRNA^{Lys1,2} per virion, reflecting their cytoplasmic ratio (Guo *et al.*, 2003; Javanbakht *et al.*, 2003; Halwani *et al.*, 2004). A portion of the incorporated tRNA^{Lys} anneals to the 18-nucleotide PBS sequence near the 5'-end of the viral genome, which is perfectly complementary to the 3'-18 nucleotides of tRNA^{Lys3}. It is not known whether tRNA annealing occurs prior to, or after, viral budding. The co-packaged tRNA^{Lys1,2} not involved in priming the virus RNA may play a role in the import of the pre-integration complex into the nucleus of the HIV-1 infected cell (Kleiman and Cen, 2004). Efficient packaging tRNA^{Lys} into viral particles is required for both annealing and optimizing viral infection of the host cells (Saadatmand and Kleiman, 2012; Guo *et al.*, 2003, 2005; Kleiman *et al.*, 2010; Gabor *et al.*, 2002).

tRNA-Like Molecules

Transfer RNA-like structures (tRNA-like structures, TLSs) are RNA or even protein sequences that have a similar tertiary structure to tRNA. tRNA-like structures have been demonstrated in bacteria (tmRNA), many plant RNA virus genomes that are linked to regulation of virus replication, as well as ribosomal recycling factors (RRF).

tmRNAs

Transfer messenger RNA (tmRNA) is a small bacterial RNA that has dual structural and functional similarities to both tRNA and messenger RNA (Zwieb *et al.*, 1999). tmRNA contains structures similar to the upper half of tRNA, including a complete acceptor stem with 3' CCA end, a T stem-loop and a degenerative D-loop (Figure 15). The 5' end of tmRNA is also processed by RNase P with typical tRNA-specific base modifications (Ray and Apirion, 1979; Keiler, 2008). tmRNA acceptor stem contains the same conserved G₃•U₇₀ wobble pair as tRNA^{Ala} and is aminoacylated with alanine by AlaRS (Komine *et al.*, 1994). In place of the anticodon stem loop is a coding sequence for a short peptide called a tag peptide. Translation of the tmRNA into a single tag-peptide requires the

Figure 15 Structure of tmRNA. The schematic diagram shows the secondary structure of tmRNA. The mRNA-like region (MLR) in standard tmRNA is a large loop containing pseudoknots and a coding sequence (ORF) for the tag peptide, marked by the resume codon and the stop codon. Overall structure of the entire tRNA domain of tmRNA complexed with SmpB is shown on the right as determined by X-ray crystallography. The SmpB mimics the missing anticodon stem-loop of a canonical tRNA.

Figure 16 Viral tRNA-like structures. Schematic diagrams show the secondary structure of tRNA with the T loop (T), D loop (D), anticodon loop (AC), variable arm (V), and acceptor stem colored (a), the secondary structure of the TYMV tRNA-like structure (TLS) (b), BMV TLS (c), TMV TLS (d). Structures analogous to those in tRNA are colored, together with the pseudoknot (PK) in the acceptor stem.

elaborate interplay of tmRNA and a tmRNA-binding protein, SmpB, and is termed trans-translation (Keiler, 2008). In the majority of bacteria these functions are carried out by a single chain tmRNA; however, in other bacterial species and mitochondria, a permuted *ssrA* gene produces a two-piece tmRNA in which two separate RNA chains are joined by base-pairing (Gur and Sauer, 2008; Hafez et al., 2013).

The bacterial quality control system monitors protein synthesis and recycles stalled translation complexes in a rescue process that involves tmRNA and trans-translation (Janssen and Hayes, 2012). For example, ribosomes that have stalled upon reaching the end of a messenger RNA that has lost its stop codon are rescued by this pathway. During rescue, tmRNA recycles the stalled ribosome, adds a proteolysis-inducing tag to the unfinished polypeptide, and facilitates the degradation of the aberrant messenger RNA (Keiler, 2008). First, alanine charged tmRNA (Ala-tmRNA) binds to EF-Tu · GTP and SmpB and this complex enters the vacant A-site of the stalled ribosome, similar to aminoacyl-tRNA but without the codon–anticodon interaction. The bound mRNA is subsequently replaced by the tag-encoding region of tmRNA allowing translation of the tag onto the nascent peptide. These tagged proteins are preferentially degraded by AAA + proteases so that they do not accumulate in the

cell. tmRNA and SmpB structurally and functionally mimics both tRNA and mRNA during these processes. Although several structural elements are known to be essential, the molecular mechanism for correct trans-translation is still not fully understood. This pathway is unique in that it employs a small RNA to prevent the accumulation of non-functional proteins produced from truncated mRNA. Although alternative rescue systems have recently been revealed, trans-translation is the only system that universally exists in bacteria and therefore is thought to play a major role in rescuing stalled translation in bacteria (Janssen and Hayes, 2012; Shpanchenko et al., 2010).

Viral tRNA-Like Molecules

Viruses commonly exploit or modify some aspect of tRNA biology. Large DNA viruses, especially bacteriophages, phycodnaviruses, and mimiviruses, produce their own tRNAs, which are used to adjust translational capacity during infection (Dreher, 2009). Retroviruses recruit specific host tRNAs for use in priming the reverse transcription of their genome. Certain positive-strand RNA plant viral genomes possess 3'-tRNA-like structures (TLSs) that are built quite differently from authentic tRNAs, yet efficiently recapitulate several properties of tRNAs

Figure 17 tRNA-like ribosomal recycling factors. Structure representation of the superposed *Thermotoga maritima* RRF (red and blue, pdb1dd5) and yeast tRNA^{Phe} (yellow, pdb2tra).

(Dreher, 2010). For example, in tobacco mosaic virus (TMV), replication takes place in two stages: synthesis of a minus RNA strand using the virus plus-strand RNA as a template and synthesis of progeny plus strand RNA using the minus strand as a template (Osman *et al.*, 2000). The 3' UTR of tobacco mosaic virus plus-strand RNA can be folded into a tRNA-like structure (TLS) containing a 3' pseudoknotted domain (D1) that mimics a tRNA acceptor branch terminating in an unpaired CCA sequence and a domain (D2) that resembles a tRNA anticodon branch (Felden *et al.*, 1996; van Belkum *et al.*, 1985). The central core, C, connects domains D1, D2, and the upstream domain D3 and determines their relative orientations. All of these TLS regions are important for minus-strand synthesis of TMV RNA (Figure 16).

The TMV 3' TLS, like those of Brome mosaic virus (BMV) and Turnip yellow mosaic virus (TYMV), can be aminoacylated. TMV constructs containing the 3'-most 182 nucleotides (D1, D2, and D3), 108 nucleotides (D1 and D2), or 38 nucleotides (D1) are all substrates for yeast histidyl-tRNA synthetase (Felden *et al.*, 1996). Experiments with BMV suggested that aminoacylation may be required for *in vivo* replication of two of the three viral genome RNAs (van Belkum *et al.*, 1985; Dreher *et al.*, 1984, 1989; Rao and Hall, 1991), but not an absolute requirement for *in vivo* replication of all tymoviruses, since TYMV chimeras containing the 3' TLS of Erysimum latent virus, which cannot be aminoacylated, are infectious in plants and protoplasts (Gultyaev *et al.*, 1994). Furthermore, aminoacylation is not required for TYMV minus-strand synthesis *in vitro* (Deiman *et al.*, 2000; Singh and Dreher, 1997; Singh and Dreher, 1998).

tRNA-Like Ribosome Recycling Factors

In addition to tRNA-like RNA structures, several proteins also mimic the structure of tRNA and play major roles in modern

biology. Most highly characterized proteins demonstrating 'tRNA mimicry' are the ribosome release/recycling factors (RRF) that function to terminate protein synthesis. Ribosome releasing/recycling factor (RRF), together with elongation factor G (EF-G), catalyzes the recycling of ribosomes after one round of protein synthesis (Franckenberg *et al.*, 2012). Bacteria have two RRFs, RRF1, and RRF2, with high specificity to decipher the three stop codons (Petry *et al.*, 2008). In the past decade, the crystal structures of the translation termination complex between the ribosome and RRFs have been determined at atomic resolution (Weixlbaumer *et al.*, 2008; Hershey *et al.*, 2012; Dever and Green, 2012; Agrawal *et al.*, 2004; Wilson *et al.*, 2005). Atomic structures of RRF from five different species, including *E. coli*, show that it is comprised of two structural domains: domain I, consisting of three long α -helix bundles, and the smaller domain II, which is an α/β motif (Selmer *et al.*, 1999; Toyoda *et al.*, 2000; Kim *et al.*, 2000; Yoshida *et al.*, 2001; Saikrishnan *et al.*, 2005). The molecule superimposes almost perfectly onto the structure of tRNA except that the amino acid-binding 3' end is missing (Figure 17). This mimicry is further supported by the identification of two classes of crucial RRF peptide motifs, P(A/V)T/SPF and GGQ, in bacteria, which were functionally equivalent to the anticodon and aminoacyl-CCA terminus of tRNA, respectively. RRF is a near-perfect structural mimic of tRNA in both size and dimensions.

Despite the tRNA-mimicry, RRFs bind to ribosomes quite differently from the way tRNA does. A three-dimensional cryo-electron microscopy map of the *E. coli* 70S ribosome-RRF complex (Borovinskaya *et al.*, 2007), together with the crystal structures of RF2 bound to ribosome (Weixlbaumer *et al.*, 2008; Jin *et al.*, 2010), indicates RRF binds further inside the intersubunit space of the ribosome, with domain II of RRF being oriented more toward the 30S ribosomal subunit and the tip of domain I of RRF is shifted toward the 50S subunit. These important conformational differences of RRF bound ribosome suggest that the mechanism of RRF in directing the dissociation of ribosome is beyond simple structural mimicry of the binding positions of tRNA. In addition to the RRFs, tRNA mimicry has also been demonstrated in proteins involved in translation initiation, elongation, as well as mRNA surveillance pathways for protein synthesis (Nakamura and Ito, 2011).

tRNA and Human Diseases

Because of the essential and multiplexed roles for tRNA in and outside of translation, alterations of tRNAs have a major impact on human health and diseases. Comprehensive inspection of alterations in tRNA and tRNA biosynthetic genes indicate that: (1) Disease-related mutations in mitochondrial tRNA are prevalent; however, (2) mutations in genes encoding cytoplasmic tRNAs are less often associated with disease, and (3) disease-related defects in modification and processing of cytoplasmic tRNA are common. This bipartite pattern may result from several differences including the different numbers of tRNA genes (22 in mitochondria, while over 600 for cytoplasmic), different number of genome copies per cell (tens to hundreds for mitochondrial, while only two nuclear genomic copies for cytoplasmic tRNAs per cell), as well as their different rates of mutation (higher in mitochondria) and functional

Table 2 Mutations of tRNA and tRNA modification enzymes in human diseases

<i>Disease</i>	<i>mt-tRNA involved</i>
ADPD/hearing loss and migraine	tRNA Gln
Adult Leigh syndrome	tRNA Val
AMDF	tRNA Val
Ataxia, PEO, deafness	tRNA Phe
Ataxia + RP + deafness	tRNA Pro
Axial myopathy with encephalopathy	tRNA Phe
Cardiomyopathy/SNHL/possible hypertension factor	tRNA Lys
CIPO	tRNA Ser (AGY)
CIPO/encephalopathy	tRNA Gly
Combined OXPHOS defects	tRNA Trp
Combined OXPHOS defects and severe multisystem disorder	tRNA Arg
CPEO	tRNA Ile, tRNA Leu (CUN)
CPEO/DEAF enhancer	tRNA Ala
CPEO/KSS	tRNA Leu (CUN)
CPEO/MM	tRNA Asn
CPEO/Motor neuron disease	tRNA Ile
CPEO/MS	tRNA Ile
CPEO/possible hypertension factor	tRNA Leu (UUR)
CPEO/Stroke/CM/Breast and renal and prostate cancer risk/altered brain pH	tRNA Leu (CUN)
CPEO + Myopathy	tRNA Glu
CPEO + ptosis	tRNA Ser (UCN) precursor
CPEO + ptosis + myopathy + exercise intolerance + diabetes	tRNA Leu (CUN)
CPEO + ptosis + proximal myopathy	tRNA Asn, tRNA Phe, tRNA Ser (AGY), tRNA Ser (UCN), tRNA Trp, tRNA Ala, tRNA Trp
DEAF	tRNA Phe
DEAF enhancer	tRNA Ala
DEAF helper mut	tRNA Arg, tRNA Cys, tRNA Ser (AGY), tRNA Thr, tRNA Cys
DEMCHO	tRNA Trp
Developmental delay, optic atrophy, cataract, hearing loss, myopathy	tRNA His
Dilated cardiomyopathy (15 bp dup)	tRNA Pro, tRNA Leu
DM	tRNA Leu (UUR)
DMD/MERRF/HCM/epilepsy	tRNA Lys
DMD/RP + SNHL	tRNA Ser (AGY)
Dopaminergic nerve cell death (PD)	tRNA Pro, tRNA Thr
Dystonia and stroke-like episodes	tRNA Lys
Encephalomyopathy	tRNA Asn, tRNA Leu (UUR), tRNA Thr
Encephalomyopathy/DEAF	tRNA Trp
Encephalomyopathy + retinopathy	tRNA Glu
Encephalopathy	tRNA Lys
Encephalopathy/MELAS	tRNA Gln
Epilepsy + ataxia + visual disturbance + deafness	tRNA Lys
EXIT	tRNA Glu, tRNA Leu (UUR), tRNA Tyr, tRNA Met
EXIT and Deafness	tRNA Phe
Extrapryamidal disorder with akinesia-rigidity, psychosis, and SNHL	tRNA Phe
Fatal neonatal lactic acidosis	tRNA Ser (UCN)
FICP	tRNA Ile
FSGS/mitochondrial cytopathy	tRNA Tyr
FSHD	tRNA Leu (CUN)
Gastrointestinal syndrome	tRNA Trp
Gestational diabetes (GDM)	tRNA Leu (UUR)
HCM severe multisystem disorder	tRNA Trp
HCM with hearing loss/possible hypertension factor	tRNA Ile
HCM + MELAS	tRNA Val
Hypomagnesemic metabolic syndrome	tRNA Ile
Hypotonia, seizure, muscle weakness, lactic acidosis, hearing loss	tRNA Met
Isolated complex I deficiency	tRNA Glu
Kearns-Sayre syndrome	tRNA Lys
KSS	tRNA Leu(UUR)
Late infantile onset fatal mito disease	tRNA Val
Leigh syndrome	tRNA Ile, tRNA Trp, tRNA Val
LHON	tRNA Gln, tRNA Leu (UUR), tRNA Glu, and tRNA Met

Abbreviations: ADPD, Alzheimer's disease and Parkinson disease; AMDF, ataxia, myopathy, and deafness; CPEO, chronic progressive ophthalmoplegia; DEAF/SNHL, deafness/sensorineural hearing loss; DEMCHO, dementia and chorea; DM, diabetes mellitus; DMDF, diabetes mellitus and deafness; FSGS, focal segmental glomerulosclerosis; GER, gastrointestinal reflux; MERRF, myoclonic epilepsy and ragged red fiber disease; MELAS, mitochondrial encephalomyopathy, lactic acidosis and stroke-like episodes; MICM, maternally inherited cardiomyopathy; MIDD, maternally inherited diabetes and deafness; MILS, maternally inherited leigh syndrome; MMC, mitochondrial myopathy and cardiomyopathy; MNGIE, mitochondrial neurogastrointestinal encephalopathy; PEM, progressive encephalomyopathy; RP, retinitis pigmentosa; SIDS, sudden infant death syndrome; SNHL, sensorineural hearing loss. mt, mitochondrial; m²G, N²,N²-dimethyl guanosine; m⁵C, 5-methylcytosine; m⁷G, 7-methylguanosine; mcm⁵s²U, 5-methoxycarbonylmethyl-2-thiouridine; m⁵U, 5-methyl uridine; m¹G, 1-methylguanosine; mcm⁵U, 5-methoxycarbonylmethyluridine; ms²t⁶A, 2-methylthio-N⁶-threonyl carbamoyl adenosine; tm⁵U, 5-taurinomethyluridine; tm⁵s²U, 5-taurinomethyl-2-thiouridine; s²U, 2-thiouridine. GARS and KARS are genes for glycyl-tRNA synthetase and lysyl-tRNA synthetase shared between cytoplasm and mitochondria. The table is extracted from the mitomap database and the references (Suzuki *et al.*, 2011; Torres and Batlle, 2014; Konovalova and Tyynismaa, 2013).

tolerance to structure/sequence alteration (mit-tRNAs are degenerative and more fragile to alteration). In addition, the multiple copies of mitochondrial genome in human cell may also allow the slow accumulation of mit-tRNA mutations through generations. As the final section of this article, we will summarize the current knowledge of defects in tRNA modification, mutations in mitochondrial tRNA in human disease, and the related therapeutic interventions.

Mitochondrial tRNA and Human Diseases

The human mitochondrial genome encodes 13 proteins, all subunits of the respiratory chain complexes involved in energy metabolism (Mercer *et al.*, 2011). These genes are translated by 22 tRNAs encoded by the mitochondrial genome (Putz *et al.*, 2007). It is the minimal set required for reading all codons. Human mitochondrial tRNAs gained interest with the rapid discovery of correlations between point mutations in their genes and various multisystemic disorders including neuromuscular and neurodegenerative disorders etc.

Recent full-spectrum surveys concluded that mutations in mt-tRNA genes contribute to the etiology of more than half of human disorders caused by mutations in the mitochondrial genome, while tRNA genes comprise only 10% of the mt-genome (Bannwarth *et al.*, 2013). A total of 249 mutations were detected in all 22 mt-tRNA genes and were found spread all over the structural domains of the corresponding tRNAs (Table 2). Nearly half of the mutations affect highly conserved nucleotides (Brandon *et al.*, 2005).

Considerable interest in mitochondrial tRNAs centers on the occurrence of diseases arising from mutations in their genes that lead to maternally inherited genetic disorders (Nakada *et al.*, 2001; Wittenhagen and Kelley, 2003; Sternberg *et al.*, 2001; Enriquez *et al.*, 1995). The diseases associated with mitochondrial tRNA mutations may arise from effects at different steps of tRNA biogenesis, such as failure in the processing of the tRNA (Levinger *et al.*, 2001), reduced stability of the tRNA (Hao and Moraes, 1997; Kelley *et al.*, 2000), or a reduction in aminoacylation (Enriquez *et al.*, 1995; Ling *et al.*, 2007; Vachon *et al.*, 1990), a reduced ability of the mutated aminoacyl-tRNA to interact with mitochondrial elongation factor Tu (mt-EF-Tu) (Ling *et al.*, 2007), and from the failure of

the tRNA to be correctly modified leading to translational defects (Kirino *et al.*, 2004). For example, MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) is a maternally inherited disease that is caused by mutations in mitochondrial genes resulting in respiratory defects arising from complex I (and complex IV) deficiencies. Approximately 90% of cases are caused by point mutations in the mitochondrial mt-tRNA^{Leu(UUR)} gene (Goto *et al.*, 1990; Kobayashi *et al.*, 1990; Gotz *et al.*, 2011; Shoffner *et al.*, 1990). The most common mutation, occurring in roughly 80% of patients, have an A to G mutation at position 3243 (A3243G) in the mt tRNA^{Leu(UUR)} gene (Goto *et al.*, 1990; Kobayashi *et al.*, 1990) and another 10% of patients have a T to C mutation at position 3271 (T3271C) in the same tRNA gene (Goto *et al.*, 1991). These mutations are believed to interfere with the efficient translation of mitochondrial complex I and IV proteins.

Emerging fundamental knowledge of the structure/function relationships of these particular tRNAs has expedited our understanding of etiology of mitochondrial disorders (Suzuki *et al.*, 2011). A point mutation (T4409C) in the gene for human mitochondrial tRNA^{Met} (mt-tRNA^{Met}) has been found to cause mitochondrial myopathy resulting in dystrophic muscles and exercise intolerance (Vissing *et al.*, 1998). This mutation results in the replacement of U8 in mt-tRNA^{Met} with a C8, at the corner of the acceptor stem and D-stem of mt-tRNA^{Met}. Examination of the U8C mutation on the structure and function of mt-tRNA^{Met} shows the mutations disrupts a critical Mg²⁺-binding site on the tRNA such that the mutant can no longer form the standard cloverleaf structure in the presence of Mg²⁺. Mt-tRNA^{Met} is the only tRNA^{Met} in human mitochondria, serving as both the initiator and elongator tRNA^{Met}, and this mutant consequently results in defective translation initiation and elongation. Combination of this mutation with other mutations in the mitochondrial DNA further increases the severity of disease and this is seen in Leber's Hereditary Optic Neuropathy (Jones *et al.*, 2008). Similarly another mutation (G4450A) leads to loss of the final base pair in the T-stem of mt-tRNA^{Met}. This mutation presents as splenic lymphoma, is largely confined to lymphocyte cells, and results in severely abnormal mitochondria leading to serious defects in energy production (Lombes *et al.*, 1998).

Another disease associated mutation (A4435G) was found to change A37 to G37 in the anticodon loop of tRNA^{Met} (Qu *et al.*, 2006). An overview of the large variety of mechanisms within translation, affected by mutations can also be found elsewhere (Suzuki *et al.*, 2011).

tRNA Modification and Human Diseases

tRNAs are heavily modified post-transcriptionally during their maturation process and many of these modifications are kingdom specific (Novoa *et al.*, 2012). In eukaryotes there are more than 50 different chemical modifications described affecting different positions on the tRNA (The tRNA Modification Database, see Relevant Websites). Most of these modifications and the enzymes responsible for catalyzing them are well described in the yeast (Phizicky and Hopper, 2010) and human homologs (Phizicky and Hopper, 2010). Particularly, the biological roles of the modifications they catalyze and the link to human diseases have been documented (Torres and Batlle, 2014).

In contrast to mitochondrial tRNA genes, diseases associated with cytosolic tRNA mutations are less frequent, however, diseases associated with aberrant modification of cytosolic tRNAs are more common. There are nearly 20 different tRNA modification enzymes that have been associated with 14 different human diseases, including neurological disorders (Intellectual disability, Familial dysautonomia, Amyotrophic lateral sclerosis, etc.), cardiac, respiratory diseases, diabetes, and cancer. For example, mutations in the tRNA modification enzymes FtsJ RNA methyltransferase homolog 1 (FTSJ1) and tRNA methyltransferase 1 (TRM1) have been found with strong association with intellectual disability. *FTSJ1* and *TRM1* genes are responsible for methylation of tRNA^{Leu} and tRNA^{Phe} at positions 32 and 34, and dimethylating guanosines (m²G) at position 26 of tRNA^{Tyr} (Townsend and Begley, 2012; Feder *et al.*, 2003). In addition, NSUN2, a tRNA methyltransferase, was first described as a downstream target of the proto-oncogene Myc and shown to be responsible for Myc-induced keratinocyte proliferation and cell cycle progression (Ador *et al.*, 1999). NSUN2 is expressed at low levels in normal tissues, but it is abundant in a range of human and mice tumor types, including squamous cell carcinoma, colorectal cancer, and breast cancer (Frye and Watt, 2006). Indeed, knockdown of NSUN2 was shown to reduce the growth of human squamous cell carcinoma xenografts in nude mice (Frye and Watt, 2006). tRNA methyltransferase homolog 12 (TRMT12) is involved in formation of wybutosine at position 37 on tRNA^{Phe} (Townsend and Begley, 2012). This gene is amplified in breast cancer cell lines and overexpressed in 26 out of 30 analyzed breast cancer tumors (Rodriguez *et al.*, 2007). TRMT2A (a paralog of TRMT12) gene is actually used as one of the five biomarkers in Mammostrat, a diagnosis tool for predicting breast cancer recurrence after tamoxifen treatment (Bartlett *et al.*, 2010). Other cancer-related tRNA modification genes include *HRG9MTD2* (Human RNA (guanine-9-) methyltransferase domain containing 2), *DNMT2* (DNA methyltransferase 2) (Schaefer *et al.*, 2009; Goll *et al.*, 2006; Himeno *et al.*, 1989; Sokabe *et al.*, 2009), *HABH8* (*HALKBH8*, human

AlkB homolog 8), and *HTRM9L* (tRNA methyltransferase 9-like) (Torres and Batlle, 2014).

Disease-associated tRNA modification could also affect mt-tRNAs. For example, both MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) and MERRF (myoclonus epilepsy associated with ragged-red fibers) are characterized by lack of modifications on mt-tRNAs. The mutations in the mt-tRNA genes that cause both diseases lie outside of the tRNA anticodon, but result in hypomodification of uridine 34. In particular, MELAS patients lack 5-taurinomethyluridine (tm⁵U) on mt-tRNA^{Leu(UAA)}, whereas MERRF patients lack 5-taurinomethyl-2-thiouridine (tm⁵s²U) on mt-tRNA^{Lys(UUU)} (Suzuki *et al.*, 2011).

Therapeutics of tRNA-Related Diseases

Various potential approaches have been suggested to treat tRNA-related human diseases. For example, a decrease of aminoacylation levels of affected mitochondrial tRNA have been demonstrated in patients' tissues and in cultured cells, as well as for pathogenic mutations in nuclear genes encoding mitochondrial aminoacyl-tRNA-synthetases (Belostotsky *et al.*, 2012). Consequently, over-expression of mitochondrial aminoacyl-tRNA synthetases or elongation factor EF-Tu rescued mutated tRNAs from degradation (Gutman, 1976; Rinaldi *et al.*, 1997; Li and Guan, 2010). Similarly, because tRNA modifications can affect translation accuracy and efficiency as well as general tRNA stability, overexpression of tRNAs could potentially be beneficial for diseases where the target tRNA cannot be properly folded or modified (Karicheva *et al.*, 2011). A very interesting approach can be learned from the MELAS system. It was found that whereas the U34 could not be modified in the mutant mt-tRNA^{Leu(UAA)}, the other mt-tRNA^{Leu} isoacceptor (UAG) carrying a mutated anticodon to (UAA) could be modified to tm⁵U34. This modified mutated mt-tRNA^{Leu} isoacceptor restored the mitochondrial deficiencies of MELAS in a lung carcinoma cell line bearing 99% MELAS mutant mt-DNA (Kirino *et al.*, 2006). Finally, gene therapy could be used to express tRNA modification enzymes in those cases with defective mutations in these enzymes (Shimizu *et al.*, 2014).

On the other hand, modulation of tRNA modification enzymes could be a promising therapeutic strategy to treat cancer. For example, the down-regulation of NSUN2 (Frye and Watt, 2006) or HABH8 (Shimada *et al.*, 2009) has been shown to inhibit squamous cell carcinoma and bladder cancer. Overexpression of HTRM9L (Begley *et al.*, 2013) could inhibit colorectal cancer. Similar strategies have also been suggested to use for targeting TRMT12 against breast cancer (Torres and Batlle, 2014; Rodriguez *et al.*, 2007). There are other suggested approaches to develop diagnosis tool kit of cancer, based on levels of the tRNA modification enzymes, or hypomodified tRNAs themselves. Practical tools for tRNA modification detection such as 'miCLIP' (methylation individual-nucleotide resolution crosslinking and immunoprecipitation) and 5-azacytidine-mediated RNA immunoprecipitation (Aza-IP) have been developed to detect m⁵C modifications in transcriptomes (Hussain *et al.*, 2013; Khoddami and Cairns, 2013). Mass spectrometry-based technique could now monitor the levels of a whole collection of tRNA modifications (Chan *et al.*, 2010).

Other targets such as *HRG9MTD2* and the levels of m¹G9 modification (in early-onset and late-onset colorectal cancer) (Berg *et al.*, 2010), the levels of m⁵U at positions 42 and 54 of tRNAs (for breast cancer) (Bartlett *et al.*, 2010), combined with direct RNA sequencing have been suggested to create a personal 'epi-tRNAomes' for cancer diagnosis (Torres and Batlle, 2014).

Other work using mitochondrial gene transfer in mice (trans-mitochondrial mice), showed that mutation of mtDNA is randomly segregated during maternal inheritance, where subsequent generations with high proportions of mutant mtDNA exclusively expressed disease-related phenotypes. They also showed that the proportion of mutated mtDNA varied markedly among the pups born to each dam, suggesting that selecting oocytes with a high proportion of normal mtDNA from mothers affected with mutant-tRNA-based mitochondrial diseases may be an effective prevention (Shimizu *et al.*, 2014).

Concluding Remarks

It has been 56 years since Francis Crick first predicted the existence of tRNA in 1958 (Crick, 1958) and since that time a tremendous amount of knowledge has been learned about tRNA biology. This progress is attributed to the collaborative work in biochemistry, molecular biology, cell biology, structure and genomic studies by scientists worldwide, which unfortunately could not be comprehensively covered in this book section. tRNAs or a precursor most likely existed in the very beginning of life on planet earth, and these nucleic acid molecules have overseen, and in fact, carried out, the transition from the primordial RNA world to the current world. As the link between amino acids and nucleic acids, tRNAs determine the genetic code, but their functions have expanded beyond protein translation and include a role in cell stress response, bacterial cell wall biosynthesis, and viral replication. Not surprisingly defects in these critical molecules are also involved in various human diseases. With the exponential rise of information about tRNA sequences in the post-genomic era, the increasing recognition of the multiplexed roles of RNAs in the modern life, we are watching a new surge of tRNA research in multiple fields from protein translation to the extreme complexity of biology.

Glossary

ARE AU-rich elements containing multiple copies of the sequence AUUUA, located in the 3' UTR.

Cap A methylated Guanosine at the 5' end of eukaryotic mRNA joined to the first base by a 5' to 5' triphosphate linkage.

Polycistronic mRNA The RNA transcript of a bacteria operon. It encodes several proteins.

UTR A sequence of nucleotides at the 5' or 3' end of mRNA that does not code for a protein product.

Messenger RNA (mRNA)

Messenger RNA is a large family of RNA molecules that are complementary to DNA molecules and convey genetic information from the DNA to be translated by ribosomes into proteins (Brenner *et al.*, 1961). mRNAs, like DNA, are nucleic acids that contain a specific sequence of nucleotides. These nucleotides are 'read' (translated) by ribosomes to assemble a polymer of amino acids, a protein. The mRNA plays a key role in the 'central dogma' of molecular biology, which deals with the transfer of sequence information from DNA to RNA to protein (Brenner *et al.*, 1961). There are a series of transfers possible as framed by this dogma. Transfers that occur normally in most cells are the transfer of information from DNA to RNA (transcription), DNA can be copied to DNA (DNA replication) or proteins can be synthesized from the information in mRNA (translation or protein synthesis). Rarely, information can be transferred from RNA to DNA, usually in the case of retroviruses (Baltimore, 1970; Temin and Mizutani, 1970). Particles of these viruses (e.g., HIV) contain two copies of RNA as their genetic information. A rare enzyme, reverse transcriptase, copies the RNA to a single strand of DNA which is then integrated into the host's DNA. Information is not transferred from proteins to either RNA or DNA. These transfers describe the general flow of biological information: DNA to RNA to protein. Messenger RNA is sometimes also called the Rosetta Stone of biological information because it is the link in transferring genetic information from DNA (nucleic acid) into protein.

While there are differences in both structure and mechanism of function of prokaryotic and eukaryotic mRNAs (Berg, 2002), there are also similarities (Figure 1). In mRNA, genetic information is encoded in a four-base alphabet of nucleotides, which form codons consisting of three bases each. Each codon codes for a specific amino acid, with the exception of stop codons which determine where protein synthesis terminates. The mRNA are translated by the ribosome which reads the codons. The start or initiator codon for both prokaryotes and eukaryotes is an AUG sequence and the sequence is read from the 5' to 3' direction. Eukaryotic mRNA generally code for a single protein (monocistronic) (Gerlinger *et al.*, 1977) while prokaryotic mRNA often code for a series of related proteins (polycistronic) on the same mRNA. Polycistronic (Gerlinger *et al.*, 1977) mRNA direct the more or less simultaneous synthesis of each of the

encoded polypeptides. For example, the *trp* operon (Hiraga and Yanofsky, 1972) is a DNA that is transcribed into mRNA that codes for six polypeptides that catalyze tryptophan synthesis. Messenger RNA are short-lived compared to DNA and the lifetime of the RNA serves as a regulatory site (Guhaniyogi and Brewer, 2001) of gene expression. After transcription, an mRNA molecule may be processed, edited, and transported prior to translation. Eukaryotic mRNA require transport and often extensive processing, while prokaryotic mRNA molecules do not (Clark and Pazdernik, 2013).

Prokaryotic mRNA Structure

Prokaryotic mRNA are synthesized in the cytoplasm and do not require transport from the nucleus (Clark and Pazdernik, 2013). They also do not require processing and can begin translation immediately after the transcription is complete. Most mRNA contain a sequence at the 5' end of the mRNA prior to the AUG start codon, termed 5' untranslated region (5' UTR) (Meijer and Thomas, 2002) and a region following the stop codon, the 3' UTR. Most prokaryotic mRNA contain a sequence in the 5' UTR to position ribosomes for translation. This sequence is named after its discoverers as the Shine–Dalgarno sequence.

Shine–Dalgarno Sequence

Most extensively studied in *Escherichia coli*, the Shine–Dalgarno (Shine and Dalgarno, 1974) sequence is a purine-rich tract of nucleotides located in the 5' UTR. This tract of 3–10 nucleotides is complementary to the pyrimidine-rich (Shine and Dalgarno, 1975) sequence of the 16S rRNA (ribosomal RNA) and is centered approximately 10 nucleotides upstream of the AUG start codon. Base pairing between the Shine–Dalgarno sequence of the mRNA and the 16S rRNA (Kozak, 1987) permit the ribosome to bind at the correct position on the mRNA in order to select the proper initiation codon. The start codon, AUG, codes for internal methionine residues as well as the initiating Met residue of the polypeptide; here the translation initiation site must be specified by more than the start codon. The Shine–Dalgarno sequence is present in nearly all prokaryotic mRNA; however, recent evidence has shown that there are prokaryotic mRNAs that lack a

Figure 1 Schematic diagram of prokaryotic (top) and eukaryotic (bottom) mRNA. Bars indicate the relative length of the regions.

Shine–Dalgarno sequence in the 5' UTR (Londei, 2005) or lack a 5' UTR completely. These mRNAs appear to be more common in primitive prokaryotes, such as archaea, in which initiation of translation on leaderless transcripts is thought to be the evolutionary oldest mechanism. The mechanism of how these prokaryotes distinguish the start codon is not known.

Polycistronic mRNA

In prokaryotic cells, a single mRNA may code for several proteins. Each message on the mRNA is contained in a single 'open reading frame,' a sequence of codons bound by start and stop codons. There are no start or stop codons within the reading frame itself. The arrangement of messages in tandem along a single strand of mRNA allows the proteins (often called gene products) to be translated simultaneously; these gene products are often related in function. Because mRNAs are single stranded, some mRNA molecules are able to base-pair within themselves and can form secondary and tertiary three-dimensional structures. These structures can regulate the synthesis of polypeptides in the polycistronic mRNA. One example of this mechanism is MS2 bacteriophage (Kozak, 1983). The A protein is coded at the 5' end of the polycistronic message, but is needed in only small quantities. The 5' end of the mRNA is often blocked by tertiary folding of the mRNA allowing only limited translation of the A protein while allowing translation to occur at more accessible sites downstream from the A gene.

Eukaryotic mRNA

Processing

Unlike prokaryotic mRNAs which are produced and translated in the cytoplasm, eukaryotic mRNAs are produced in the

nucleus and translated in the cytosol, requiring transport. In addition, eukaryotic mRNAs undergo processing (Alifano *et al.*, 1994; Lodish, 2000), described in detail elsewhere. We will mainly focus on the structural features of the mRNA resulting from this processing. These 'pre-mRNA' undergo a number of modifications, the most striking of which is splicing, involving the excision of nonexpressed intervening sequences, following which flanking sequences are spliced or joined together. The mRNA itself also undergoes capping and addition of a poly(A) tail, the structural features of which are described below.

Cap

The cap is an altered nucleotide attached to the 5' end of mRNA (Figure 2). 5' capping is essential for creating mature mRNA for efficient translation. Capping occurs in the cell nucleus and is required for export of the mRNA to the cytosol for translation. The 5' cap itself consists of a guanosine residue methylated in the 7 position and attached to the 5' end of the mRNA through a 5' to 5' triphosphate linkage (Figure 2). Additional methylation may occur at the first two nucleosides of the transcript. In most multicellular eukaryotes, the first nucleoside is methylated at the O2' position, the 2' hydroxyl group of the first ribose sugar. Additional methylations can occur at the 2' hydroxyl group of the ribose sugar of the second nucleoside, and if the first nucleoside is an adenosine, it may also be methylated at the N6 position. The 5' cap functions to regulate nuclear export of the mRNA, prevent degradation by exonucleases, promote 5' exon excision, and promote efficient translation of the mRNA.

The cap is the binding site for eukaryotic initiation factor 4E (eIF4E) and this interaction is believed to be the rate-limiting step for protein synthesis for most eukaryotic mRNA.

Figure 2 Chemical structure of m7G cap and first nucleotide. The linkage between the m7G and first nucleotide is a 5' to 5' triphosphate. Possible additional phosphorylation sites are indicated.

5' UTR

The 5' UTR, or leader sequence, begins at the 5' terminal end and ends one nucleotide before the AUG start site. In eukaryotes, this tends to be long, anywhere from 100 to several thousand nucleotides. In warm-blooded eukaryotes, this is a G C rich region with a G + C percentage of about 60%. This long stretch of nucleotides contains features often used to regulate translation of the mRNA. Unlike prokaryotic mRNA, eukaryotic mRNA do not contain a Shine–Dalgarno sequence, but usually contain the Kozak consensus sequence (ACCAUGG), which contains the initiator AUG and is the optimum sequence for ribosome initiation. While termed the untranslated region, a portion of the 5' UTR is sometimes translated to make a protein product which can then regulate translation of the main coding region of the mRNA. These coding sequences, termed upstream open reading frames (uORF) contain their own initiation codon and are fairly common as a means to regulate translation of the mRNA, occurring in 35–50% of all human mRNA (Chatterjee and Pal, 2009).

In other mRNA, the 5' UTR region is untranslated but can form secondary structures to regulate translation. One of the most studied examples of this is the iron response element (IRE). Iron levels are maintained by translation of proteins involved in iron storage and metabolism. The 5' UTR contains a stem loop structure, the IRE, which binds iron regulatory proteins 1 and 2 (This element also occurs in the 3' UTR of some mRNA coding for proteins involved in iron regulation.). When cellular iron levels are low, iron response protein (IRP) binds to the IRE element and blocks translation by steric hindrance of the ribosome binding. At higher iron levels, the IRE RNA element binds iron (Ma *et al.*, 2012) causing release of the IRP protein and enhanced binding of protein synthesis initiation factor 4F (eIF4F) to increase synthesis of proteins such as ferritin, required for storage of iron. In general, secondary structures in the 5' UTR are thought to inhibit translation by making scanning of the ribosome from the 5' cap to the ORF AUG more difficult.

A further means of regulating translation through mRNA structure is the internal ribosome entry site (IRES). These nucleotide sequences allow the ribosome to bind internally on the 5' UTR, rather than at the cap. First discovered in viruses, these sequences have since been found in cellular mRNA, often those involved in cell growth regulation and mitosis. The secondary structures of these regions can be quite complex and to date there is no consensus motif. The mechanism of IRES-dependent translation is much better understood in viruses than in cellular mRNA and continues to be an area of active research (Hellen and Sarnow, 2001).

3' UTR

The 3' UTR is comprised of a series of bases following the stop codon that are not translated into protein. Like the 5' UTR, this region contains numerous regulatory elements which can influence translational efficiency, mRNA stability, mRNA localization, and polyadenylation. The poly(A) tail is a sequence of -A- residues added to the 3' end of the mRNA after transcription. In humans, the average length of the 3' UTR is approximately 800 nucleotides, but can range from 60 to about 4000 nucleotides in eukaryotes. This long sequence in the 3' UTR reflects the complexity of regulation. The 3' UTRs contain binding sites for both microRNA (miRNA) and proteins. In general, longer 3' UTRs are associated with reduced gene expression since they contain more protein and miRNA binding sites that can inhibit translation. Overall these sites can lead to a highly complex regulation of gene expression and mRNA stability. Further, the 3' UTR contains sequences that promote the binding of proteins that associate the mRNA with the cytoskeleton, transport from the nucleus and other types of mRNA localization (Matoulikova *et al.*, 2012).

AU-Rich Elements and Stem Loops in mRNA

AU-rich elements (AREs) are 50–150 bases in length and usually contain multiple copies of the sequence AUUUA.

These elements are binding sites for proteins and these proteins, in response to different intracellular and extracellular signals, can promote mRNA decay, affect mRNA stability (Winzen *et al.*, 2004), or promote translation. It provides rapid means of cell growth regulation, differentiation, and adaptation. Transcripts encoding cytokines, proto-oncogenes, growth factors, and tumor suppressors are among the mRNA utilizing this type of mechanism (Winzen *et al.*, 2004).

Stem loops occur in the 3'UTR as well as the 5' UTR and can provide a scaffold for protein binding. IREs described earlier also occur in the 3' UTR of mRNAs that encode proteins involved in cellular iron metabolism. The mRNA transcript containing the IRE is either stabilized or degraded depending on the intracellular iron concentration which affects protein binding (Svoboda and Di Cara, 2006).

MicroRNA Response Elements

miRNA response elements are sequences often contained in the 3' UTR to which miRNAs bind. miRNAs are naturally occurring short, noncoding RNA molecules, usually between 18 and 25 nucleotides in length that bind to mRNA and regulate gene expression. This interaction is mediated by proteins in the miRNA-RNA Induced Silencing Complex (RISC). Several hundred miRNAs have been identified in mammals, although many of their mRNA targets have not been characterized. The miRNA interaction with miRNA response elements usually involves partial base pairing between the miRNA and the mRNA within the 3' UTR and results in translational repression (Macfarlane and Murphy, 2010).

The miRNA-RISC complex can also disrupt the closed loop between the cap and Poly(A) tail that forms during translation of the mRNA which exposes the mRNA to exonucleases and decapping enzymes resulting in mRNA decay. These interactions allow for differential gene expression at developmental stages and in various tissues.

Poly(A) Tail

Eukaryotic mRNAs have a sequence of 100–200 adenylic acid residues attached to the 3' UTR designated the poly(A) tail. This sequence is added posttranscriptionally and is essential for efficient translation and mRNA stability (Goss and Kleiman, 2013). The poly(A) tail is a binding site for poly(A) binding proteins (PABPs), which interact with other factors to affect translation, decay, and export of mRNA. PABPs interact with translation initiation factors bound to the 5' UTR cap to promote circularization of the mRNA which allows for efficient recycling of ribosomes during translation. Polyadenylation is regulated by sequences within the 3' UTR, including cytoplasmic polyadenylation elements (CPEs). These CPEs are uridine-rich sequences which bind other proteins to contribute to polyadenylation activation and repression.

mRNA and Disease

Mutations in eukaryotic mRNA have been identified with a number of diseases. These mutations can affect the open reading frame or coding sequence of the mRNA and result in

mutated proteins which can be defective in function (Liu *et al.*, 1999; Wen *et al.*, 2009; Wiestner *et al.*, 1998). In addition, both the 5' UTR and the 3' UTR provide regulatory elements for expression of the mRNA and mutations in these regions can lead to disease states by altering translation of the mRNA (Scheper *et al.*, 2007), either overexpression or repression of key proteins (Calvo *et al.*, 2009), changing the stability of the mRNA (Hollams *et al.*, 2002), or possibly altering the localization of the mRNA (Holt *et al.*, 2007). These mutations alter key features of the mRNA required for protein interactions.

There are a number of cases where mutations in the 5' UTR cause altered translation and lead to human disease. The most studied and best understood case is the dysregulation of ferritin translation (Goforth *et al.*, 2010). A mutation in the IRE element (described above) decreased binding of the IRP protein and increased ferritin translation leading to hereditary hyperferritinemia-cataract syndrome (Roetto *et al.*, 2002). The IRE element has been identified in the 5' UTRs of other mRNAs with disease implications. Amyloid- β precursor protein (APP) is implicated in Alzheimer disease and Down syndrome (Folin *et al.*, 2003). APP is cleaved into peptides which are the main components of neurotoxic amyloid plaques and overexpression of APP is due to increased translation.

Mutations in the 5' UTR IRES have also been associated with human disease (Chatterjee and Pal, 2009). Cellular IRES containing mRNA include a number of oncogenes, including members of the myc gene family, growth factors such as VEGF, and the anti-apoptotic protein Bag1. It is not surprising that deregulation of these IRES may affect the progression of cancer and other diseases. Many of the IRES contain mRNA function under stress conditions and this is particularly important for tumor progression where IRES translation of growth factors such as VEGF and FGF2 functions under hypoxic conditions. Tumor growth leads to the center of the tumor becoming hypoxic and increased vascularization is necessary for continued tumor growth. IRES-driven expression of growth factors is necessary for increased vascularization and resulting growth. Other point mutations in the 5' UTR have been associated with human disease: a mutation in the connexin-32 IRES causes Chalcot-Marie-Tooth disease, a neurodegenerative disease (Hudder and Werner, 2000), and a point mutation in the 5' UTR of BRCA1 has been identified in aggressive breast cancer (Signori *et al.*, 2001).

The 3' UTR contains a number of elements involved in gene expression and mutation of these elements can lead to disease states, usually through affecting protein binding. Dysregulation of ARE-binding proteins through mutations in the AU-rich regions can lead to tumorigenesis and hematopoietic malignancies. An expanded number of trinucleotide CTG repeats in the mRNA of dystrophin myotonia protein kinase causes myotonic dystrophy and other 3' UTR elements have been linked to alpha thalassemia, neuroblastoma, and congenital heart defects among other diseases (Halvorsen *et al.*, 2010).

Because UTR sequences often contain regulatory motifs that are common to members of the same metabolic family, they could provide an opportunity for development of highly specific RNA-based therapies to target a single or related genes (Wilkie *et al.*, 2003).

The Interplay between Eukaryotic mRNA Degradation and Translation

W Hu, Whitehead Institute for Biomedical Research, Cambridge, MA, USA

© 2016 Elsevier Inc. All rights reserved.

The destruction of mRNA is essential for proper regulation of gene expression. All mRNA must be destroyed to ensure that nuclear regulatory decisions are manifested as cytoplasmic events. In other words, ceasing mRNA transcription in response to environmental or physiological cues is irrelevant as long as cytoplasmic mRNA exists and is translated. From this, it can be said that mRNA decay contributes significantly to the proteomes' overall architecture by allowing cells to quickly adapt to environmental and physiological changes. Although much is known about mRNA decay in eukaryotes, understanding how the process is modulated is far from complete.

In this section, we first discuss our current understanding of eukaryotic mRNA decay. Then we put mRNA degradation in the context of mRNA translation, which is another important cytoplasmic event of gene expression, as these two events are known to be tightly integrated with each other for decades. In the last few years, many studies have concentrated on this relationship as a means to elucidate regulation of mRNA degradation. From this, two views have arisen. The first suggests that mRNA must be removed from ribosomes to be destroyed in ribosome-free areas, such as P-bodies. The other view proposes mRNA decay occurs in concert with protein synthesis. Here we summarize our current understanding of how eukaryotic mRNA decay interconnects with mRNA translation, and then analyze the data that have led to these two diametrically opposed models of where mRNA decay occurs within the cell. Finally, we attempt to reconcile these two views and suggest important areas for future investigation.

Overview of Eukaryotic mRNA turnover

Cytoplasmic mRNAs are destroyed by two major pathways. Both are initiated by the exonucleolytic digestion of the 3' poly (A) tail (a process termed deadenylation). Deadenylation is a key regulatory step in mRNA half-life determination because its rate is highly variable among transcripts. In some cases, deadenylation leads to mRNA destruction 3'–5' by the cytoplasmic exosome. In other cases, deadenylation causes the rapid removal of the 5' 7mGpppN cap and digestion of the transcript body 5'–3' (reviewed in [Coller and Parker, 2004](#)). Which pathway predominates is not clearly understood. Most likely transcript, tissue, and species specific differences dictate the predominate pathway employed. In this article, we focus exclusively on the deadenylation-dependent decapping pathway since it has been extensively characterized and its relationship to translation is more established than that of the cytoplasmic exosome-dependent pathway.

As mentioned, deadenylation is the first step of mRNA decay and is often thought to be rate limiting. This reaction is carried out by several enzymes (deadenylases) that digest the poly(A) tail in a 3'–5' direction. Generally, mRNA deadenylation is biphasic, the first step is initiated by the deadenylase dependent

poly(A) nuclease 2 (PAN2). Following this initial trimming event, the bulk of the tail is digested by the enzyme complex CCR4/POP2/NOT ([Yamashita et al., 2005](#)). Other deadenylases, however, exist including poly(A)-specific ribonuclease (PARN), Nocturin, and Angel proteins (reviewed in [Goldstrohm and Wickens, 2008](#)). It would appear, then, that deadenylation is facilitated by a seemingly redundant class of enzymes. Diversity in transcript stability might occur in part by the manner in which these enzymes achieve transcript specificity. For example, 3'UTR-binding proteins and miRNAs can enhance deadenylation by tethering a specific enzyme ([Giraldez et al., 2006](#)).

In yeast as well as in mammalian cells, deadenylation usually leads to destruction of the mRNA. In some systems, deadenylation can lead to translational storage of the mRNA. Although still unclear, it is thought that the poly(A) tail mediates its effect on mRNA translation and decay by way of an interaction between the poly(A)-binding protein (PAB) and the translation initiation factor eIF4G ([Coller et al., 1998](#); [Jacobson and Peltz, 1996](#)). Deadenylation serves to displace PAB from the mRNA thereby liberating its protective and/or translational stimulatory function.

In the cases where transcript destruction follows deadenylation, once the mRNA tail has been trimmed to a length no longer supporting PAB binding, the 7-methyl-guanosine cap structure is rapidly cleaved from the mRNA's 5' end. The decapping reaction requires the enzymatic activity of the DCP2 protein. Enzymatically, the pyrophosphatase activity of DCP2 cleaves the alpha-beta bond of the 5' cap liberating m⁷GDP and leaving a 5' monophosphate on the transcript. *In vitro*, DCP2 is sufficient for this activity ([Lykke-Andersen, 2002](#)). Although simple in chemistry *in vitro*, the *in vivo* orchestration of mRNA decapping requires a suite of proteins including DCP1, DHH1(RCK/p54), Hedls (only in metazoans), Pat1p (P100), Lsm1–7, Lsm12, Scd6 (Trailerhitch...), and Edc1–3 (reviewed in [Franks and Lykke-Andersen, 2008](#)). The precise function(s) of these factors is murky. Some decapping activators like LSM1–7 and Hedls may serve structural roles in promoting binding of DCP2 to the mRNA. Others like DHH1 and PAT1 are hypothesized to promote DCP2's accessibility to the cap by dissociating factors bound at the mRNA 5' end, such as eIF4F ([Coller and Parker, 2005](#); [Chu and Rana, 2006](#)). Irrespective of their true function, the complexity of this process indicates that mRNA decapping is tightly regulated. Control of decapping makes sense since this step of decay commits the mRNA to destruction and unlike deadenylation is largely irreversible although exceptions have been documented (reviewed in [Schoenberg and Maquat, 2009](#)).

Subsequent to decapping, the transcript is quickly and efficiently destroyed by the 5'–3' exonuclease, XRN1. This enzyme is highly processive and decay intermediates are hard to detect ([Stevens, 2001](#)). To date, no regulation of XRN1 activity has been detected, thus, it is generally thought that the 5'–3' exonucleolytic decay is not a rate-limiting step in turnover.

mRNA Degradation is Intimately Linked to Translation

All mRNA must and will succumb to decay. Transcript decay is, therefore, a default state. The spectrum of observed half-lives most likely represents acceleration or deceleration of this default rate. The translatability of an mRNA is a critical contributor to its overall stability (reviewed in [Franks and Lykke-Andersen, 2008](#); [Jacobson and Peltz, 1996](#)). Specifically, an inverse correlation has been established showing efficiently translated mRNAs have longer half-lives; while poorly translated mRNAs are unstable. These findings suggest that a major determinant of mRNA stability is the translation machinery. Curiously, however, modulation of each specific sub-step of translation, i.e., initiation, elongation, or termination, is perceived to have disparate effects on mRNA's half-life. It is important to note that this perception is based largely on the manner of analysis (see below).

The when and where of mRNA decapping and exonucleolytic decay has been the subject of some debate. Models for where mRNA decay takes place are in part based on the distinct manner in which translational inhibition affects mRNA decay. Experimental evidence has suggested two possibilities. On one side data seems to indicate that before decapping can occur, the translational machinery must be liberated and then the message is destroyed in specialized places within the cell. On the other side, there are data to suggest that mRNA never leave polysomes and are degraded co-translationally. In the following sections we highlight the work of many individuals whose observations have generated these two distinct views.

The Ying-Yang of Translational Initiation and Transcript Stability

Translational initiation is posited to be in direct competition with mRNA decapping (reviewed in [Franks and Lykke-Andersen, 2008](#)). From a priori view, this hypothesis makes sense because both translational initiation and mRNA decapping are dependent on factors binding on or near the 5' cap ([Cougot et al., 2004](#)). This theory is also supported by experimental data. In a simplified view, translation initiation consists of three major events: first recognition of the cap by eIF4F, which is composed of eIF4E, eIF4G, and eIF4A; second, recruitment of the 40 S ribosomal subunit; third, scanning of the 40 S ribosomal subunit to the first AUG (reviewed in [Kapp and Lorsch, 2004](#)). Altering the rate of any of these three events has a profound effect on mRNA half-life. For instance, mutations in eIF4F reducing its affinity for the cap result in rapid and efficient deadenylation and decapping ([Schwartz and Parker, 1999](#)). Similarly, inhibiting 40 S ribosomal subunit recruitment and scanning accelerates mRNA deadenylation and decapping. For example, inactivation of eIF3, thereby blocking 40 S recruitment ([Kapp and Lorsch, 2004](#)), results in rapid mRNA decay ([Heikkinen et al., 2003](#)). *Cis*-acting RNA structures that inhibit 40 S ribosomal subunit scanning also accelerate mRNA turnover ([Muhlrads et al., 1995](#); [Coller and Parker, 2005](#)). Lastly, the context of the AUG start codon influences mRNA stability. Specifically, nucleotide changes around the translation start codon predicted to decrease translational efficiency also dramatically destabilize reporter transcripts ([LaGrande and](#)

[Parker, 1999](#)). Taken together these correlations between translational initiation and mRNA decapping predict that decreasing ribosome occupancy on the 5'UTR allows the decay machinery to associate more efficiently with the transcript. Moreover, these data suggest that the translation initiation factors and decapping factors vie for the mRNA *in vivo*.

A direct competition between decapping and eIF4E has been documented *in vitro*. Purification of DCP1 from yeast extracts allows decapping to be monitored *in vitro* (presumable because purification of DCP1 brings along the decapping enzyme DCP2). Addition of recombinant eIF4E protein efficiently inhibits *in vitro* decapping mediated by the purified decapping enzyme ([Schwartz and Parker, 2000](#)). In conjunction with the aforementioned *in vivo* work, these data have led to the model that dissociation of eIF4E is required before mRNA decapping can occur. Importantly, this notion is supported by genetic analysis. Specifically, loss of eIF4E will restore the decapping activity when it is partially impaired genetically (i.e., DCP1^{Ts}; [Schwartz and Parker, 2000](#)). Collectively, these results indicate that the mRNA decapping enzyme (Dcp2/Dcp1) and eIF4E are probably in competition for the 5'-end cap structure on an mRNA. Clearly, mRNA decapping is stimulated by loss of eIF4E function, but it is also important to note that *in vivo* inhibition of translational initiation in any manner also greatly enhances deadenylation rate. The effects of translation rate on deadenylation have remained unexplored.

Undoubtedly there is a positive correlation between the efficiency of translational initiation and mRNA stability. The displacement of eIF4E from the cap, therefore, is proposed to be a necessary first step in mRNA decapping (reviewed in [Coller and Parker, 2004](#)). At this point, it is important to note that the inverse correlation between translation rate and mRNA decapping does not hold true under every physiological condition. For example, cellular stress can have profound effects on translational initiation and mRNA decay. Under these extreme conditions the predictable correlation between translation and decay does not occur. Specifically, translational initiation is inhibited when cells are deprived of glucose ([Ashe et al., 2000](#)). Despite this, mRNAs are dramatically stabilized rather than destabilized ([Hilgers et al., 2006](#)). On the other hand, amino acid deprivation also powerfully inhibits translation initiation (ref) but mRNAs are greatly destabilized under this condition. Lastly, the unfolded protein response also triggers repression of translation ([Scheuner et al., 2001](#)), but this stress does not affect mRNA stability at all ([Hilgers et al., 2006](#)). One possible explanation for these discrepancies is that each distinct stress alters one or more of the mRNA decay factors. Alternatively, each stress might change mRNP dynamics and therefore the manner by which it is perceived by the decay machinery. It seems likely, therefore, that a more detailed understanding of how cellular stress impacts mRNA stability will shed more light on the complex interplay between decay and translation.

Translation Elongation and mRNA Turnover

It is postulated that once an mRNA is engaged in elongation, ribosomes provide a protective quality that insulates the

transcript from decay (Jacobson and Peltz, 1996). This theory, however, is controversial. Unlike translational initiation where slowing the process enhances decay, the manner in which elongation is perturbed dramatically influences the result obtained. For example, treating cells with the translation elongation inhibitor, cycloheximide (a drug that freezes ribosomes on mRNA), results in a significant inhibition of decay in budding yeast and high eukaryotes (Beelman and Parker, 1994; Ross, 1995). Similar results are obtained when elongation is stopped using genetic mutation. Specifically, depleting charged tRNAs by inhibiting maturation of their 3' end will dramatically stabilize mRNA (Peltz *et al.*, 1992). In both cases, blocking elongation is suggested to inhibit decapping (Beelman and Parker, 1994), deadenylation still occurs, albeit at a slightly reduced rate (Hilgers *et al.*, 2006). It is important to point out, that both of these procedures do not kinetically slow elongation, rather, they freeze ribosomes on mRNA and block elongation altogether. Paradoxically, slowing the rate of translation elongation is similar to slowing translational initiation in that it destabilizes mRNAs. For example, rare codons are recognized by tRNAs with low concentrations within the cell, thus, mRNAs with rare codons have a relatively slow translation rate compared to the mRNAs with cognate normal codons. The presence of rare codons within an mRNA saturates the transcript with ribosomes and dramatically shortens half-life (Caponigro *et al.*, 1993; Hu *et al.*, 2009). Slowing ribosome translocation in this manner, therefore, destabilizes mRNAs. One possible explanation for these differences is that freezing mRNA on ribosomes may 'lock' the transcript in an RNP conformation that is resistant to mRNA decay factors. Conversely slowing elongation enhances decay by a yet unknown mechanism.

Translation Termination and mRNA Stability

Eukaryotic mRNA translation termination requires two release factors, eRF1 and eRF3. Translation termination process can influence mRNA half-life. Specifically, it was observed that the N-terminal domain of eRF3, which is not required for translation termination, can interact with Pab1, and this interaction is involved in modulating mRNA stability (Hosoda *et al.*, 2003). Disruption of this interaction results in translation-dependent stabilization of mRNA caused by decreased deadenylation rate (Hosoda *et al.*, 2003). Interestingly, it was further found that certain deadenylase complexes can also bind to the same site on Pab1 that is involved in the interaction with eRF3 (Funakoshi *et al.*, 2007). Thus, it has been postulated that eRF3 can regulate mRNA deadenylation by competitively binding to the Pab1, which then modulates the recruitment and activation of deadenylase complexes (Funakoshi *et al.*, 2007). In addition to the release factors, other proteins that can modulate translation termination can also influence mRNA stability. For example, a recent characterized protein named Tpa1 can interact with the two release factors and regulate the readthrough of stop codons (Keeling *et al.*, 2006). Interestingly, although the detailed mechanisms still remain elusive, knocking out this protein can have decreased deadenylation rate and increased mRNA stability (Keeling *et al.*, 2006). Collectively, these results suggest that

mRNA translation termination can result in mRNP conformational changes that can influence mRNA stability, likely via modulating mRNA deadenylation.

Where Does Eukaryotic mRNA Degradation Occur Within the Cell?

In recent years, understanding where mRNA degradation occurs within the cell has been given a great deal of scientific investigation. The thought is that insight into how the large repertoire of observed mRNA half-lives is achieved may come from knowing when and where degradation occurs within the cytoplasm. At present, there are two different views on where mRNA degradation takes place. The first comes from the discovery that mRNA decapping and decay factors aggregate into punctuate, microscopically visible structures. These structures have been given the epitaph of processing bodies or P-bodies for short. Importantly, P-bodies do not contain ribosomes nor do they contain most translational initiation factors. What they do contain is the full complement of decapping proteins, certain mRNA decay intermediates, and in higher eukaryotes, the miRNA machinery (reviewed in Franks and Lykke-Andersen, 2008; Parker and Sheth, 2007). In conjunction with the aforementioned findings that mRNA translation is generally positively correlated with half-life, these data have led to a popular 'two-step' model for regulating transcript stability in which ribosome dissociation first occurs, then the mRNA is trafficked to P-bodies where mRNA decapping ensues (reviewed in Franks and Lykke-Andersen, 2008; Parker and Sheth, 2007). We refer to this model as the 'mRNA cycle hypothesis,' because it is postulated that mRNA can cycle in and out of polyribosomes and into a quiescent state that can be either stored/reutilized or degraded (Brenques *et al.*, 2005). A second model supported in the literature, is that mRNA decay does not involve a fundamental transition between a polyribosome-bound state and a translationally repressed state, but rather occurs co-translationally (Hu *et al.*, 2009). This hypothesis dates back almost 20 years (Beelman and Parker, 1994; Mangus and Jacobson, 1999), but has lacked strong experimental evidence until recently. Nonetheless, both models are supported but have their limitations. Here, we will examine these two models in detail and at the end attempt to provide a unifying theory.

The mRNA Cycle Hypothesis – From Polysome to p-Bodies (and Perhaps Back)

The theory that translation and decay are partitioned events is based in part on the aforementioned distinct effects translation initiation versus elongation have on mRNA half-life. The mRNA cycle hypothesis suggests that mRNA is translated and then at some point becomes translationally silenced and moved into a state of quiescence. Once this inactive state is achieved, the mRNA can either be destroyed or perhaps reutilized in response to certain cues. In theory, translational repression of mRNA makes sense from a logistical stand point. The 5'-cap structure is occupied by a suite of proteins that promote 40 S ribosome joining. At some

point, DCP2 must have access to the cap and 5'UTR, and thus it seems logical that the 5' end is remodeled and initiation factors displaced (Steiger *et al.*, 2003). It is predicted that the downstream consequence of this remodeling must be translational repression, as manifest by ribosome dissociation.

The RNA cycle hypothesis is rooted in studies of translational initiation and its effect on decay. As discussed in the previous section, Schwartz and Parker (1999) found that mutations in eIF4F result in mRNA destabilization. Cap binding by eIF4F, therefore was proposed to be in competition with mRNA decapping. Similar results were seen when other aspects of initiation were compromised, including 40 S joining and AUG recognition. Moreover, *in vitro* experiments demonstrated that addition of purified eIF-4E could reduce decapping in cell extracts (Schwartz and Parker, 2000). The combined findings were interpreted as a direct competition between eIF4E and DCP2 exists. A corollary of this hypothesis is that translational repression, defined as ribosome dissociation, is required before mRNA decapping.

The mRNA cycle model is also supported by the discovery that several decapping regulators influence mRNA translation. Specifically, DHH1 and PAT1 were shown to be bona fide translational repressors in yeast and humans (Coller and Parker, 2005; Chu and Rana, 2006). Consistent with the notion, DHH1 is homologous to factors implicated in maternal mRNA storage (reviewed in Rajyaguru and Parker, 2009) thus decapping was hypothesized to be similar to posttranscriptional events that occur during early development (Coller *et al.*, 2001). The nature of how mRNA decapping regulators influence mRNA translation is still unknown, but has been proposed to inhibit translation initiation (Coller and Parker, 2005).

Other aspects of mRNA decay are also thought to result in translational silencing, and possible ribosome dissociation. Specifically, mRNA deadenylation can lead to translational repression (Huarte *et al.*, 1992). This is especially well documented during development. The poly(A) tail and its binding protein, PAB, are hypothesized to interact with the 5' cap via a protein interaction with eIF4G. Poly(A) is popularly believed to stimulate translation by way of this 'close-loop' (Jacobson and Peltz, 1996). Collectively, the first step of mRNA decay, deadenylation, would be predicted to result in a loss of translational efficiency. It is important to note, however, that controversy exists whether deadenylation is a cause or effect of translational repression in some context.

P-bodies, above all things, bolstered the notion that ribosome dissociation is required for mRNA decapping and that these events are similar to storage events that occur in other contexts (reviewed in Parker and Sheth, 2007; Rajyaguru and Parker, 2009). The discovery of P-bodies dates back to 1997 when Bashkirov *et al.* (1997) cloned the mouse homolog of the known 5'-3' exonuclease Xrn1. Using mouse E10 fibroblast cells, it was observed that mXrn1 localized to punctuate cytoplasmic structures. At this time, the authors proposed that these structures may represent either sites for RNA turnover or sites in which the enzyme is stored until used. P-bodies were rediscovered in 2002 when Eystathioy *et al.* (2002) found that the human auto-antigen protein, GW182, was also found in cytoplasmic granules. Although it was not clear at this time,

GW182 is a critical factor in mediating miRNA translational control (Tritschler *et al.*, 2010). One year later, a flurry of studies simultaneously demonstrated that, in the addition to XRN1, the major decapping factors also are found in cytoplasmic foci (many refs). Sheth and Parker (2003) extended this analysis by showing that mRNA decay intermediates co-localized with these granules in a manner that is dependent on the enzymatic activity of yeast XRN1. Similar results were seen in humans (Cougot *et al.*, 2004). Thus the aggregation of decay factors in granules was suggested to be of functional significance and that these foci represented the place where mRNAs were degraded.

P-bodies are devoid of ribosomes and other vital translational initiation factors (Sheth and Parker, 2003; Cougot *et al.*, 2004). Coupled with the aforementioned results indicating decapping is in competition with translational initiation, it was further proposed that mRNA must be removed from ribosomes and trafficked to a P-body before decay ensues (reviewed in Franks and Lykke-Andersen, 2008). Indeed the very term P-bodies, or processing bodies was coined, in part, to draw similarity to P-granules or polar bodies, known sites of mRNA storage in germ-lines, oocytes, and embryos (reviewed in Parker and Sheth, 2007; Rajyaguru and Parker, 2009). Consistent with this, P-bodies have also been suggested to contain translational quiescent mRNA (Bregues *et al.*, 2005; Parker and Sheth, 2007; Franks and Lykke-Andersen, 2008). In mammalian systems, the miRNA machinery co-localizes to P-bodies further supporting a model in which P-bodies are sites of mRNA storage. In yeast, stress conditions like glucose deprivation result in global shut-down of mRNA translation and mRNA decay. This correlates with an increase in P-body size and abundance. An increase in P-body size has been interpreted as an influx of mRNA into these structures (Bregues *et al.*, 2005; Sheth and Parker, 2003). Taken together, mRNA decapping has hypothesized to require removal of mRNA from the translational apparatus followed by packaging into P-bodies where either decay or storage ensues.

The RNA cycle model is very provocative, but there are still many questions left to be answered. For instance, one important feature of this hypothesis is that DCP2 and eIF-4E are in direct competition with each other for cap access. While this competition is clear *in vitro*, *in vivo* the relationship between DCP2 and eIF4E is more complex. Specifically, if a simple competitive relationship existed, then loss of eIF4E function would result in promiscuous mRNA decapping independent of deadenylation. Although perturbations in initiation result in accelerated decapping, in all cases when initiation is impaired (i.e., initiation factor mutants, AUG context changes, and *cis*-acting initiation blocks) decapping is not uncoupled from deadenylation. Indeed, loss of deadenylation by *ccr4* mutation stabilizes non-translating mRNAs. Rather, loss of eIF-4F function results in rapid deadenylation followed by rapid decapping (Schwartz and Parker, 1999). These data indicate that loss of eIF-4E is not sufficient to elicit decapping directly, rather dissolution of the initiation complex sensitizes the mRNA toward decay in a fashion that is still unknown. In this light, the notion that eIF-4E displacement is a critical event in decapping stimulated by deadenylation requires reinvestigation.

The RNA cycle hypothesis is also based on the notion that removing mRNAs from ribosomes accelerates their decay. Based on this, polysomes would provide a protective quality to the transcript, for example, sequestering the message from P-bodies. While generally, impeding translational initiation promotes rapid mRNA decay, important caveats exist. For instance, there is no correlation between changes of translation status and mRNA stability under conditions of stress known to impede protein synthesis (see above). Moreover, little evidence exists that ribosomes protect the mRNA from destruction. In fact, slowing translation elongation by use of rare codons saturates the message with ribosomes, but, paradoxically, greatly enhances its decay by the normal deadenylation-dependent decapping machinery. It appears then that an mRNA that never has ribosomes is degraded quickly, and an mRNA that is saturated with slowly moving ribosomes is also degraded quickly. Thus, there is no obvious need for the mRNA to dissociate from the translational machinery in order to be degraded efficiently (see below).

Lastly, an important aspect of the RNA cycle hypothesis is that once mRNA leaves ribosomes they enter P-bodies. From a quantitative point of view, it is still unclear to what extent mRNA decapping and 5'–3' exonucleolytic decay occur in ribosome-free areas in the cell. Moreover, it is unclear how much of the decapping complex assembles into P-bodies versus the soluble cytosol. In some cases, it has been suggested to be only a minor fraction. For instance quantification of the P-body protein Ago2 in mammalian cells revealed that less than 5% of total Ago2 is localized in P-bodies (Leung *et al.*, 2006). Second, P-bodies, whose abundance correlates well with events that enhance translation repression and mRNA decay, are not required for either of these events. Specifically, in both yeast and higher eukaryotes, several groups have shown that P-body formation can be uncoupled from mRNA turnover and translation repression (Sweet *et al.*, 2007; Decker *et al.*, 2007; Eulalio *et al.*, 2007). Together, these data demonstrate that the function of P-bodies remains enigmatic. Clearly, however, the aggregation of decapping factors into P-bodies is not required for normal rates of mRNA turnover.

In summary, the RNA cycle hypothesis is provocative. It provides a simple explanation for how mRNA turnover and translation are interconnected. Importantly, however, significant caveats exist suggesting that mRNA turnover is not as simplistic as the model suggest.

Parting on Polysomes

A second model that has emerged in the literature is that message decay takes place co-translationally. In other words, mRNA decapping and 5'–3' exonucleolytic digestion occur primarily on polyribosomes and not in a ribosome-free state (e.g., a P-body). The hypothesis that mRNAs are destroyed on polysomes is not new. In most cases, however, this scenario has only been observed in special cases; specifically albumin and β -tubulin mRNA (Pastori *et al.*, 1991; Theodorakis and Cleveland, 1992). Nonetheless, small clues are seen throughout the literature. Early evidence was first seen yeast. As mentioned in previous sections, treating yeast cells with the translational elongation inhibitor cycloheximide leads to the

dramatic stabilization of mRNAs. Recent interpretations of this effect are that the mRNA is sequestered in polyribosomes under these conditions and away from P-bodies (reviewed in Parker and Sheth, 2007; Franks and Lykke-Andersen, 2008). Interestingly, however, Beelman and Parker (1994) investigated mRNA decay in cells treated with cycloheximide and found the mRNA accumulated as a slightly shorter species over time. Although this finding wasn't further characterized, they proposed the truncated mRNA was the result of decapping and digestion up to a ribosome stalled at the AUG. Consistent with the hypothesis of co-translational decapping/decay, it was also found that in humans decapping activity co-sediments with polysomes (Wang *et al.*, 2002a,b). Mangus and Jacobson (1999) observed that decay intermediates similar to those observed in P-bodies were also associated with polyribosomes. Lastly, we provided additional supportive by showing that the majority of decapping is observed while the transcript is saturated with ribosomes (Hu *et al.*, 2009). Collectively, these data argue that under normal physiological conditions, mRNA decapping and 5'–3' exonucleolytic digestion occur on polyribosomes. A corollary of this hypothesis is that a transition into a translational repressed state, a predicted by the RNA cycle hypothesis, is not required for efficient mRNA decay.

Like the RNA cycle hypothesis, the model of co-translational decay also has important caveats to mention. First, numerous reports have shown that events like deadenylation inhibit protein synthesis (Huarte *et al.*, 1992; Thompson *et al.*, 2000; Beilharz *et al.*, 2009), yet no apparent difference in ribosome association can be seen for mRNA before and after deadenylation in our analysis. It is important to note here that polysome analysis provides direct physical evidence for the binding of ribosomes to an mRNA, it does not provide any information about translation rate. For example, it has been documented that miRNA targets are saturated with ribosomes, yet no protein output is detectable (Maroney *et al.*, 2006; Nottrott *et al.*, 2006). It is unclear how this is possible, but most likely indicates that there are enigmatic mechanisms of translational control that have yet to be revealed. Indeed in our own analysis we cannot conclude if nonadenylated mRNAs are translating at the same rate as fully adenylated mRNA. A clear and important area of future investigation is to correlate ribosome occupancy with adenylation status and protein output. Perhaps this analysis will shed light on this unexpected finding.

Second, it is clear that the decapping regulators DHH1 and PAT1 inhibit protein synthesis most likely by altering translational initiation (Coller and Parker, 2005) and that mutations in initiation factors can accelerate decapping. In this regard, it is important to realize that polysome analysis is a gross measurement of ribosome-associated mRNPs. Subtle changes such as rearrangement of the mRNA's 5' UTR are beyond the detection limit of this assay, unless they result in dramatic changes in polysome association.

Lastly, the contribution of initiation factors to polyribosome association/maintenance is still unclear. In recent years it has been observed that loss of initiation factor function *in vivo* has only a mild effect on polyribosome formation. Thus, it is formally possible that 5'UTR remodeling can occur with little or no appreciable change in ribosome occupancy. The explanation for this paradox remains unclear, but might indicate that initiation factors are only rate limiting for

translation under certain circumstances or during early events in protein synthesis before the establishment of polyribosomes.

What Does It All Mean?

The interplay between translation and message decay is of great importance for understanding the overall regulation of gene expression. As discussed in the previous two sections, there are two points of view. One is that most mRNA decay occurs after ribosome dissociation and perhaps in P-bodies. The other suggests that mRNA never leave ribosomes and decay is co-translational. Both hypothesizes are based on clear experimental observations. Neither model is perfect and both have important caveats for consideration. In the end, the truth most likely lies somewhere in between.

Biochemical data indicate that polyribosomes represent a major site of mRNA decapping within the cell under normal growth conditions. Importantly, however, evidence also exists to suggest that decay occurs, at some level, in P-bodies. We propose that all mRNA degradation is initiated on polyribosomes at the step of deadenylation. Where subsequent transcript degradation occurs is a function of the messages' translation rate versus relative to its decapping rate. We hypothesize that deadenylation does indeed reduce translational efficiency (Huarte *et al.*, 1992) perhaps through loss of the PAB, Pab1p (Jacobson and Peltz, 1996), or association of decapping regulators such as DHH1 and PAT1 (Coller and Parker, 2005). These events allow for the remodeling of the 5'UTR and deposition of a decapping complex. Under normal conditions, where mRNA translation is robust, mRNA decapping will occur on polyribosomes because it is kinetically faster than ribosomal run-off. We envision that decay in P-bodies is restricted to certain circumstances, such as under stress (when global translation is altered) or for mRNA populations in which ribosomal run-off is kinetically faster than mRNA decapping. Under conditions in which mRNA translational initiation or decapping are rate limiting (such as during stress), ribosomal run-off would predominate even in the absence of mRNA deadenylation and decay would be predicted to occur on ribosome-free mRNAs which may assemble into cytoplasmic P-bodies. Under normal conditions, however, we propose that remodeling of the 5' UTR and deposition of the decapping complex is faster than the rate at which the mRNA can be cleared of ribosomes. In this regard, the mRNA is degraded co-translationally.

Perspectives

Despite all that we have learned about mRNA decay in the past 20 years, there are still many mysteries. For instance, we still do not really understand how mRNA half-lives are determined for individual mRNAs. We are aware of elements that promote stability or instability, but by and large, it is unclear how these mRNA features really work. Perhaps central to this line of study is determining exactly how mRNA deadenylation rate is regulated. Deadenylation initiates mRNA decay and it clearly occurs at a message-specific rate, thereby setting the transcript's

overall half-life. Despite its importance, the control of mRNA deadenylation rate is still largely unexplored. We do know that mRNA deadenylation occurs on polyribosomes (Hilgers *et al.*, 2006). As mentioned previously, altering the translation rate of a message greatly enhances deadenylation. It would be of great interest to explore how mRNA translation modulates mRNA deadenylation rate.

Regarding decapping, this step of decay commits the message to be destroyed. Although a large collection of information on the decapping reaction has been gathered, such as characterization of the decapping enzyme, identification of global and message-specific decapping activators, and the potential interplay between the decapping enzyme and translation initiation factors, several outstanding and fundamental questions remain. For instance, the decapping complex is composed of more than 10 proteins in addition to the Dcp2/Dcp1 but we do not even have the simplest understanding of the temporal and special relationship of these factors during to each other and during the process of decay. Moreover, it has been documented that the same mRNA can have different stabilities under different environmental conditions (e.g., normal physiological conditions vs. stress conditions), thus determining how the decapping activity is regulated under different conditions will further provide insights into the regulation of mRNA decapping.

Third, what is the role of P-bodies? P-bodies are evolutionarily conserved ribosome-free cellular foci with mRNA decay factors and certain mRNA decay intermediates. Interestingly, there is a reverse correlation between mRNA decay status and the formation and sizes of P-bodies under certain conditions (Franks and Lykke-Andersen, 2008; Parker and Sheth, 2007). It has been demonstrated by many different labs that P-bodies are not required for mRNA decay nor for translational repression (Chu and Rana, 2006; Decker *et al.*, 2007; Eulalio *et al.*, 2007; Sweet *et al.*, 2007). The contribution, therefore, of P-bodies to mRNA metabolism is yet to be understood but of clear importance.

Lastly, how is mRNA half-life determined in the context of on-going translation? Clearly subtle changes in messages translatability can lead to dramatic changes in the messages' stability. For instance, dramatic disruption of translation events can elicit quality control pathways like nonsense-mediated mRNA decay (NMD), non-stop decay, or No-Go decay. It is important also to think about how subtle changes alter the way the normal pathway responds to the message. For instance, slowing initiation accelerates decay. Slowing elongation accelerates decay. Indeed, it appears that if translation is aberrant at any step, mRNA decay accelerates. Perhaps is it most appropriate to think of the normal degradation machinery as a monitor for the quality of protein synthesis events; its function is to respond when translation goes awry. mRNAs are constantly associated with proteins, from its birth to death (reviewed in Moore, 2005). As we learn more, it seems that this mRNP has to be just right in order to facilitate mRNA metabolism events, like splicing, transport, and translation. It is tempting to speculate that changes to the mRNP occur during mRNA translation and this signals that the message is no longer translating efficiently and it is time for it to be cleared from the polyribosome pool. Perhaps the key event is deadenylation itself, which is a default reaction that

dramatically impacts the mRNP structure and translatability of the mRNA. As the tail is shortened, translation rate changes and this is 'sensed' as a translational aberrancy. Once this occurs the messages is cleared from the cytoplasm by other decay factors. In this light, perhaps the normal degradation machinery becomes a critical aspect of monitoring the quality of gene expression as well as a regulator of its overall levels. Time will tell.

Glossary

Argonaute (AGO) Proteins that are guided to mRNA targets by small silencing RNAs including microRNAs.

Dicer Ribonuclease III endonuclease that liberates microRNA–microRNA* duplexes from precursor microRNAs (pre-miRNAs). Dicer associates with partner proteins containing multiple double-stranded RNA-binding domains (dsRBDs), such as transactivation-response RNA-binding protein (TRBP), protein kinase R-activating protein (PACT), and Adenosine deaminase acting on RNA 1 (ADAR1) in mammals. The plant Dicer (DCL1, Dicer-like 1) cleaves primary microRNAs (pri-miRNAs) into pre-miRNAs, as well as pre-miRNAs into microRNA–microRNA* duplexes.

Drosha The nuclear RNase III endonuclease in animals that cleaves the base of a stem–loop structure contained in pri-miRNAs to produce a pre-miRNA. Drosha associates with partner proteins DGCR8 or Pasha, which contain dsRBDs. The Drosha–DGCR8/Pasha complex is called Microprocessor. Plants lack Drosha and its partner proteins.

dsRNA-binding domain (dsRBD) Approximately 70 amino acid domain that binds to double-stranded RNA (dsRNA). Proteins containing dsRBDs are called double-stranded RNA-binding proteins (dsRBPs). Many of the protein factors in the miRNA pathway have dsRBDs.

microRNA (miRNA) Approximately 22 nucleotide long, small noncoding RNAs that mediate posttranscriptional gene silencing. miRNAs are produced in a form of microRNA–microRNA* duplex by Dicer cleavage of pre-miRNA. microRNA* is the partially complementary strand to the miRNA strand. The miRNA strand becomes single stranded within the Argonaute protein after the miRNA* strand is released from the Argonaute protein, and forms mature miRNA-induced silencing complex (miRISC) capable of binding and silencing target mRNAs.

Precursor miRNA (pre-miRNA) Approximately 60–70-nt long stem–loop RNAs produced from pri-miRNAs by Drosha cleavage. Pre-miRNAs have a single-stranded loop that connects two partially complementary sequences, which will become the miRNA strand and the miRNA* strand after Dicer cleavage. Pre-miRNAs have a 5' monophosphate and a two nucleotide 3' overhang.

Primary miRNA (pri-miRNA) RNA polymerase II transcripts containing 7 methylguanosine cap at the 5' end, polyadenylated tail at the 3' end, and a stem–loop structure that serves as a substrate for Drosha in animals and DCL1 in plants. Pri-miRNAs are processed to liberate a pre-miRNA and two unstable, single-stranded by-products.

Ribonuclease III (RNase III) Double-stranded RNA-specific endoribonuclease that generates products with two nucleotide 3' overhangs, a 5' monophosphate and a 3' hydroxyl group. Drosha and Dicer are Ribonuclease III enzymes.

RNA-induced silencing complex

(RISC) Ribonucleoprotein complex that consists of a small RNA guide strand bound to an Argonaute protein and mediates silencing of target RNAs. RISC containing miRNA is called miRISC.

Seed sequence Seven nucleotide motif in the nucleotide positions 2–8 of microRNA, counting from the 5' end. Seed sequence is organized by Argonaute to determine target-RNA recognition and binds target mRNAs.

Small interfering RNA (siRNA) Approximately 21 nucleotide long, small noncoding RNAs that mediate posttranscriptional gene silencing. siRNAs are produced by Dicer cleavage of precursor long dsRNA or short hairpin RNA (shRNA). The siRNA duplex becomes single stranded (the guide strand) within the Argonaute protein after one of the strands (the passenger strand) is released from the Argonaute protein. The siRNA guide strand bound by Argonaute forms mature siRNA-induced silencing complex (siRISC) capable of cleaving target RNAs.

Introduction

microRNAs (miRNAs) are small noncoding RNAs (~22 nucleotide long) found in animals, plants, and some viruses, which function in posttranscriptional gene silencing (Figure 1(a)). The miRNA functions are important in every aspect of biology, including cell physiology, cell cycle control, metabolism, immune response, apoptosis, development, differentiation, stress response, and aging. miRNAs bind target mRNAs via sequence complementary and silence the target mRNAs by translational suppression or mRNA destabilization (Figure 1(b)). miRNAs are generated in a highly regulated

pathway, where conserved protein factors play essential roles. Human genome contains over 1800 miRNAs, which target as many as 60% of human mRNAs. Mutations in the miRNA genes and the miRNA pathway genes are associated with human diseases. Small interfering RNAs (siRNAs) are also small noncoding RNAs (~21 nucleotide long), but they are distinct from miRNAs. siRNAs are typically produced from exogenous long double-stranded RNA (dsRNAs) such as virus and transposon or from artificially introduced short hairpin RNAs (shRNAs). siRNAs silence the target RNAs by cleaving them. In this article, biogenesis and function of miRNAs are reviewed.

Figure 1 miRNA structure and the mode of miRNA binding to its target (a) miRNA structure. miRNA is approximately 22 nucleotide long, small RNA with 5' monophosphate and 3' hydroxyl at its ends. The sequence of the nucleotide positions 2–8 counting from the 5' end is called 'seed' sequence and used for binding to the target mRNAs. (b) miRNA binds its target mRNAs that contain sequence complementarity to its seed sequence. The complementary site in the target mRNA is called 'seed match' site. The binding of human miR-96 and one of its target mRNAs, AQP5, is shown.

Biogenesis of miRNAs in Animals

miRNAs are Transcribed by RNA Polymerase II

miRNAs are encoded in genomic DNA. miRNAs are first transcribed as long primary miRNA (pri-miRNA) transcripts containing hairpin loop structure by RNA polymerase II (Figure 2). Pri-miRNAs are transcribed either from independent genomic transcription units or from the introns of protein-coding genes. Pri-miRNAs have a 7-methylguanosine cap and a 3' polyA tail (Cai *et al.*, 2004; Lee *et al.*, 2004a; Rodriguez *et al.*, 2004). About half of all mammalian miRNAs originate from polycistronic units containing multiple discrete hairpin loops from which mature miRNAs are produced (Altuvia *et al.*, 2005).

Drosha Cleaves Pri-miRNAs into Pre-miRNAs

Pri-miRNAs are cleaved in the nucleus by the Ribonuclease III (RNase II)I enzyme Drosha, aided by its partner protein DGCR8 (DiGeorge syndrome critical region gene 8) in mammals or Pasha in flies and worms, into an approximately 60–70-nt long hairpin RNA, called precursor miRNAs (pre-miRNAs) (Figure 2; Lee *et al.*, 2003, 2004a; Denli *et al.*, 2004; Gregory *et al.*, 2004; Han *et al.*, 2004; Landthaler *et al.*, 2004).

DGCR8 and Pasha contain two dsRNA-binding domains (dsRBDs) (Figure 3).

The complex containing Drosha and DGCR8/Pasha is called Microprocessor complex. The Microprocessor complex also contains a variety of cofactors such as RNA helicases and heterogeneous nuclear ribonucleoproteins (hnRNPs). These auxiliary factors may function to control the activity, specificity, and localization, of Drosha cleavage.

In the Microprocessor complex, DGCR8/Pasha orients the catalytic RNase III domains of Drosha to liberate pre-miRNA hairpins from pri-miRNA by cleaving RNA about 11 nts from the hairpin base, a junction between single-stranded RNA (ssRNA) and dsRNA, which corresponds to one helical turn into the stem (Han *et al.*, 2006). pri-miRNAs can produce several pre-miRNAs for polycistronic miRNAs. pre-miRNAs

bear the hallmarks common to all RNase III products: 2-nt 3'-overhang end with 5'-monophosphate and 3'-hydroxyl.

Exportin-5/Ran-GTP Complex Transports Pre-miRNAs from Nucleus to Cytoplasm

The Exportin-5/Ran-GTP complex forms a baseball mitt-like structure, recognizes the ends and the stem of pre-miRNAs, and transports them from the nucleus to the cytoplasm via the nuclear pore (Figure 2; Yi *et al.*, 2003; Bohnsack *et al.*, 2004; Lund *et al.*, 2004; Okada *et al.*, 2009).

Dicer Cleaves Pre-miRNAs into miRNA-miRNA* Duplexes

In cytoplasm, the second RNase III enzyme, Dicer, cleaves pre-miRNAs into approximately 22 nucleotide long miRNA-miRNA* duplexes comprising approximately 20 bp with 2-nt 3'-overhang ends (Figure 2; Bernstein *et al.*, 2001; Grishok *et al.*, 2001; Hutvagner *et al.*, 2001; Ketting *et al.*, 2001). The two strands of the duplex correspond to the mature miRNA and its miRNA*, a partially complementary small RNA derived from the opposite arm of the pre-miRNA stem. Both miRNA and miRNA* strands have 5'-monophosphate and 3'-hydroxyl (Figure 1(a)).

In mammals and worms, the single Dicer enzyme functions in converting pre-miRNAs into miRNA-miRNA* duplexes. In flies, which has two Dicer enzymes, Dicer-1 cleaves pre-miRNAs into miRNA-miRNA* duplexes, while Dicer-2 functions in biogenesis of siRNA duplexes (Lee *et al.*, 2004b). Like Drosha, Dicer recognizes defined RNA structures of pre-miRNAs and then cleaves at a fixed distance away from the base of the pre-miRNA stem, cutting off the loop joining the 5' and 3' arms to produce approximately 22 nucleotide mature miRNA-miRNA* duplexes.

As Drosha binds with partner proteins DGCR8/Pasha encompassing tandem dsRBDs, Dicer also associates with partner proteins containing multiple dsRBDs (Figures 2 and 3). Mammalian Dicer has three partner proteins, transactivation-response RNA-binding protein (TRBP), protein kinase R-activating protein (PACT), and Adenosine deaminase acting

Figure 3 Domain structures of the miRNA pathway proteins. Domain structures of human proteins are shown. Drosha and Dicer are Ribonuclease III enzymes, DGCR8, TRBP, PACT, and ADAR are their partner proteins. Argonaute 1–4 are Argonaute proteins; RIIIa and RIIIb, Ribonuclease III domain; dsRBD, dsRNA-binding domain; Helicase, Helicase domain; Platform, Platform domain; PAZ, PAZ domain; Heme-binding, Heme-binding domain; WW, tryptophan–tryptophan (WW) motif; Z-DNA binding, Z-DNA binding domain; Adenosine Deaminase, Adenosine deaminase domain; N, N domain; Mid, Mid domain; Piwi, Piwi domain.

Figure 2 miRNA pathway. miRNA pathway in animals. miRNAs are transcribed from genomic DNA by RNA polymerase II (RNA pol II) as pri-miRNAs bearing a 7-methylguanosine cap and polyA tail. Drosha, assisted by its partner protein DiGeorge syndrome critical region gene 8 (DGCR8) in mammals or Pasha in flies and worms, cleaves pri-miRNAs into pre-miRNAs in the nucleus. Exportin-5 (Exp-5), assisted by Ran-GTP, transfers pre-miRNAs from the nucleus to the cytoplasm. Dicer, assisted by its partner proteins TRBP, PACT, and ADAR1 in mammals or Loquacious in flies, cleaves pre-miRNAs into miRNA–miRNA* duplexes. The miRNA–miRNA* duplexes are loaded into Argonaute with the aid of the chaperone machinery HSP90 and HSC70. Then miRNA* is released from the Argonaute complex and miRNA becomes single stranded within the Argonaute complex. The mature complex composed of an Argonaute protein and a single-stranded small silencing RNA is called RISC, and when the small silencing RNA is miRNA, the complex is called miRISC. miRISC binds target mRNAs using the sequence complementarity between the seed region of miRNA and the target mRNAs. The seed region is located at the nucleotide positions 2–8 of miRNA counting from the 5' arm of miRNA. The binding sites (seed match sites) are usually located within the 3' untranslated region (3' UTR), rather than 5' UTR or open reading frame (ORF), of mRNAs. miRISC silences the target mRNAs by repressing its translation or destabilizing the mRNAs. For the translational repression, miRISC inhibits the initiation step of translation. For mRNA destabilization, miRISC causes deadenylation of poly A tails of the mRNA targets by the CCR4–NOT exonuclease, leading to decay of the mRNAs. Other molecular mechanisms for target mRNA suppressions are also proposed.

on RNA 1 (ADAR1) (Chendrimada *et al.*, 2005; Haase *et al.*, 2005; Lee *et al.*, 2006; Ota *et al.*, 2013). Fly Dicer-1 associates with Loquacious-PA and Loquacious-PB (Forstemann *et al.*, 2005; Jiang *et al.*, 2005; Saito *et al.*, 2005). The Dicer partner proteins can enhance miRNA processing by Dicer by increasing the affinity or enzymatic turn over of Dicer for pre-miRNAs and refine the substrate specificity of Dicer (Chakravarthy *et al.*, 2010; Fukunaga *et al.*, 2012; Ota *et al.*, 2013). For a subset of pre-miRNAs, the Dicer partner proteins can also alter the position of Dicer-mediated cleavage within the pre-miRNAs, producing different miRNA isoforms (isomiRs) with different length compared with the miRNA isoforms produced by Dicer alone or Dicer bound by alternative partner proteins (Fukunaga *et al.*, 2012; Lee and Doudna, 2012).

miRNA-miRNA* Duplexes are Loaded to Argonaute

miRNA-miRNA* duplexes are loaded into Argonaute proteins (Figure 2). The loading step is supported by the chaperone machinery HSC70-HSP90 consuming ATP, which presumably accelerates the conversion of the Argonaute protein conformation from a closed to a more open structure receptive to binding miRNA-miRNA* duplexes (Iwasaki *et al.*, 2010; Miyoshi *et al.*, 2010).

After the miRNA* strand is released, the Argonaute complex becomes functional miRNA-induced silencing complex (miRISC) encompassing the single-stranded miRNA strand capable of binding and silencing target mRNAs. Mismatches between the miRNA and miRNA*, particularly in the miRNA seed sequence (nucleotide positions 2–8) region, promote release of the miRNA* strand (Tomari *et al.*, 2007; Kawamata *et al.*, 2009).

Argonaute loading of the miRNA-miRNA* duplexes occur in such orientation that the miRNA strand, instead of the miRNA* strand, is maintained at the later step. The inherent features of the miRNA-miRNA* duplex determine the loading orientation. The thermodynamic asymmetry of the miRNA duplex is one important parameter (Khvorova *et al.*, 2003; Schwarz *et al.*, 2003). The strand whose 5' end is less stably base-paired will be more frequently chosen as the miRNA strand or the guide strand. In contrast, the strand whose 5' end is more stably base-paired serves as the miRNA* strand or the passenger strand, and is excluded from the Argonaute and is eventually degraded. The sequence of the 5' end of the strand is another important parameter. A strand with 5' uridine is favored as a miRNA strand.

Flies have two Argonaute (Ago1 and Ago2) and miRNA-miRNA* duplexes are selectively loaded to Ago1, while siRNA duplexes are loaded to Ago2. Mammals have four Argonaute proteins (AGO1, AGO2, AGO3, and AGO4), which exhibit similar preferences for the structures of small RNA duplexes, suggesting that there is not clear selective loading mechanism in mammals.

Domain Structures of the miRNA Pathway Proteins

Both Drosha and Dicer have two RNase III domains (RNase IIIa and RNase IIIb) followed by the C-terminal dsRBD (Figure 3). The two RNase III domains form an intramolecular heterodimer and make staggered cleavages in the two arms of a

pri-miRNA or pre-miRNA (Zhang *et al.*, 2004; Macrae *et al.*, 2006). Cleavage by RNase III domains results in 2-nt 3'-overhang end with a 5'-terminal monophosphate, and a 3'-hydroxyl in the product RNA.

In addition, Dicer has an amino-terminal 'helicase' domain, a central atypical dsRBD (previously known as DUF283), a platform domain, and a PAZ domain. PAZ domains are found in both Dicer and Argonaute proteins and recognize the characteristic 2-nt 3'-overhang of pre-miRNA and miRNA-miRNA* duplex left by Drosha and Dicer cleavage, respectively (Lingel *et al.*, 2003, 2004). In addition, the platform domain and the PAZ domain of Dicer recognizes the 5' monophosphate on pre-miRNAs (Park *et al.*, 2011; Fukunaga *et al.*, 2014; Tian *et al.*, 2014).

The entire Dicer protein forms an L-shaped structure (Wang *et al.*, 2009; Lau *et al.*, 2009, 2012; Taylor *et al.*, 2013). The two RNase III domains and the C-terminal dsRBD are positioned in the body, while the PAZ domain is located at the head of the longer axis of the L. The helicase domain forms a clamp-shaped structure at base.

DGCR8 has a heme-binding domain and two dsRBDs. A tryptophan-tryptophan (WW) motif is located within the heme-binding domain. DGCR8 forms homodimer via a heme-binding domain interaction, where the WW motif functions as a platform for extensive dimerization interaction (Senturia *et al.*, 2012). Heme binding to DGCR8 is required for efficient pri-miRNA processing by the Drosha-DGCR8 complex (Faller *et al.*, 2007; Weitz *et al.*, 2014).

TRBP and PACT have three dsRBDs and are paralogous proteins. In addition to their role in the miRNA pathway by association with Dicer, these two proteins are involved in interferon response. Currently it is not known if there is any crosstalk between the miRNA pathway and the interferon pathway.

Like TRBP and PACT, ADAR1 has three tandem dsRBDs. ADAR1 also has N-terminal two tandem Z-DNA binding domains and a C-terminal adenosine deaminase domain. The Z-DNA binding domains bind to Z-DNA, the left-handed conformer of DNA. The adenosine deaminase domain converts adenosine residues into inosine (A-to-I editing) in RNA substrate. The deaminase catalytic activity is not required for ADAR1 to bind Dicer and promote its miRNA biogenesis activity (Ota *et al.*, 2013).

Human Argonaute1, 2, 3, and 4 are highly paralogous proteins encompassing N domain, PAZ domain, Mid domain, and Piwi domain. The N domain is required for releasing of miRNA* strand after Argonaute is loaded with a miRNA-miRNA* duplex (Kwak and Tomari, 2012). The PAZ and Mid domains anchors the 3'- and 5'-ends of the guide miRNA strand, respectively. The Piwi domain adopts RNase-H like fold (Elkayam *et al.*, 2012; Schirle and Macrae, 2012). The piwi domain of Ago2, but not those of the other three Argonaute proteins, can cleave target mRNAs when the guide miRNA strand or the guide siRNA strand has extensive complementarity to the target RNAs.

miRNAs Suppress Target mRNAs

The Argonaute protein loaded with a single-stranded miRNA (miRISC) binds target mRNAs via sequence complementarity.

Here, only a limited region of the miRNA sequence, called the 'seed' sequence, a 7-nt long sequence located at the nucleotide positions 2–8 counting from the 5' end of the miRNA, is used for the complementary binding (Figures 1 and 2; Lewis *et al.*, 2005). Sequences that are complementary to the seed sequence, called 'seed matches,' are bound by miRISC. The complementary binding between a seed sequence and a seed match sequence contributes most of the energy for target binding (Haley and Zamore, 2004; Ameres *et al.*, 2007; Wee *et al.*, 2012). In the Argonaute–miRNA complex, the nucleotide bases of the seed sequence of miRNA are prearranged for binding to mRNA targets (Elkayam *et al.*, 2012; Schirle and Macrae, 2012). Seed matches can occur in any region of an mRNA but are more likely to silence target mRNAs effectively when they are in the 3' UTR (Grimson *et al.*, 2007; Gu *et al.*, 2009; Forman and Collier, 2010). The small size (7 nt) of the seed sequence means that a single miRNA can regulate many of different mRNAs. Conversely, a single mRNA encompassing multiple seed matches for different miRNAs can be bound and regulated by multiple different miRNAs. In fact, approximately 60% of all protein-coding genes in mammals are predicted to be regulated by miRNAs (Friedman *et al.*, 2009). Thousands of other mRNAs seem to have experienced negative selection to avoid seed matches with miRNAs.

miRISC binding to mRNAs causes suppression of translation or degradation of the mRNAs. Despite extensive studies, the precise molecular mechanism by which miRISC causes translational repression and mRNA degradation are not well known. Many distinct mechanistic models for miRNA suppression of target genes have been proposed (Fabian *et al.*, 2010), including (1) inhibition of translation initiation by inhibiting interaction between an mRNA 5' cap and the 40S Ribosome subunit. (2) Inhibition of translation initiation by inhibiting 60S Ribosomal subunit joining. (3) Inhibition of translation elongation by inhibiting 80S Ribosome movement. (4) Causing premature termination of translation by inducing Ribosome drop-off. (5) Degradation of produced protein by co-translational nascent peptide degradation. (6) Destabilizing mRNA by enhancing deadenylation of polyA tail by CCR4-NOT exonuclease. (7) Degrading mRNA by cleaving them. (8) Decreasing mRNA abundance available for translation by sequestration mRNA in discrete cellular compartment called Processing-bodies (P-bodies). (9) Inhibition of transcription by reorganizing chromatin structure. Among these, the models (1) and (6) seem to have more supporting data than the others (Figure 2). It is likely that multiple of these proposed mechanisms operate and choice of the mechanisms might dependent on species, cellular context, Argonaute proteins, and miRNA–target context.

Some Argonaute proteins, such as mammalian AGO2, have catalytic activity to cleave RNA targets, while other Argonaute proteins, such as mammalian AGO1, AGO3, and Ago4, do not. When the miRNA loaded to the cleavage competent Argonaute proteins has extensive sequence complementarity to target mRNAs, then the Argonaute complex can cleave the target mRNAs. However, animal miRNAs generally do not have enough sequence complementarity to their endogenous mRNA targets and thus target mRNA regulation via cleavage is rare in animals.

miRNA Turnover

For rapid changes in miRNA expression profiles during development and when responding to cellular condition changes, turnover of mature miRNA is needed. During miRNA maturation in the cytoplasm, uptake by the Argonaute protein is thought to stabilize the guide miRNA strand. The released miRNA* strand is preferentially destroyed and miRNA–miRNA* duplexes that are not efficiently loaded to Argonaute for some reasons are believed to be unstable and degraded.

When Argonaute-loaded miRNA has unusually extensive complementarity to target RNAs, that miRNA is degraded by unknown mechanisms (Ameres *et al.*, 2010). Then the Argonaute protein becomes empty and can accommodate a next miRNA–miRNA* duplex (De *et al.*, 2013). In *Caenorhabditis elegans*, 5'→3' exoribonuclease XRN-2, degrades miRNA (Chatterjee and Grosshans, 2009).

Alternative Biogenesis Pathways of miRNAs

As described above, in the standard pathway of miRNA biogenesis, miRNAs are produced by sequential cleavage by the two RNase III enzymes, Drosha and Dicer. However, some miRNAs are produced by alternative pathways, which bypass one of the two cleavage steps.

Some pre-miRNAs, called mirtrons, are produced by splicing and debranching instead of Drosha cleavage (Okamura *et al.*, 2007; Ruby *et al.*, 2007). A few pre-miRNAs are produced directly by transcription by RNA polymerase II, independent of Drosha, and has a 7-methylguanosine cap at the 5' end and the 3' end is defined by transcription termination and lacks polyA tail (Xie *et al.*, 2013).

Like cropping of pri-miRNAs by Drosha can be bypassed for some pri-miRNAs, dicing of pre-miRNAs can also be bypassed. Pri-miR-451 is cropped into pre-miR-451 by Drosha in the standard pathway. However, the hairpin of pre-miR-451 in zebrafish and mice is too short to be recognized by Dicer; instead, it is directly loaded into AGO2 for further processing by AGO2 and Poly(A)-specific ribonuclease into a mature miR-451 within AGO2 (Cifuentes *et al.*, 2010; Yang *et al.*, 2010; Yoda *et al.*, 2013).

In the standard pathway, the miRNA strand is retained in the Argonaute protein while the miRNA* strand is released and degraded. There are cases in which both miRNA and miRNA* strands are functional (Okamura *et al.*, 2008, 2009; Seitz *et al.*, 2008; Czech *et al.*, 2009; Ghildiyal *et al.*, 2010). In such cases, a miRNA–miRNA* duplex can be loaded to Argonaute proteins in two different orientations: one orientation that favors the miRNA strand retention and the miRNA* strand release, the other orientation that favors the miRNA* strand retention and the miRNA strand release. Relative expression levels between the miRNA strand and the miRNA* strand reflect relative retention ratio in the Argonaute proteins and vary widely among tissues, indicating that strand selection factors other than sequence features might exist. Furthermore, for select pre-miRNAs, the loop strand, which is cleaved off by Dicer as a ssRNA and is degraded, can be loaded to Argonaute by unknown mechanism and silence target mRNAs (Okamura *et al.*, 2013). Thus, pre-miRNAs can be multifunctional, with individual strands adopting different fates within the miRNA biogenesis pathway.

miRNAs in Plants

Fungi do not have miRNAs. Plants have distinct miRNA sequences, miRNA precursor structures and mechanisms of biogenesis, compared with those in animals. These suggest that the miRNA pathway evolved independently between in animals and plants (Jones-Rhoades *et al.*, 2006). miRNAs are present in the earliest diverging extant lineage of animal life, sponge *Amphimedon*, suggesting possible correlation between the emergence of miRNAs and multicellularity of animals (Grimson *et al.*, 2008). In contrast, the unicellular alga *Chlamydomonas* has miRNAs and the biogenesis factors that are similar to those in higher plants, showing that the miRNA pathway evolved before multicellularity in plants (Molnar *et al.*, 2007).

Like in animals, plant miRNAs are transcribed by RNA polymerase II and pri-miRNAs have 5' 7-methylguanosine cap and 3' polyA tail (Jones-Rhoades and Bartel, 2004; Xie *et al.*, 2004, 2005; Zhang *et al.*, 2005). Unlike animals, plants lack Drosha enzyme. Instead of the sequential processing of pri-miRNAs by Drosha and then Dicer in animals, plant pri-miRNAs are cleaved twice by Dicer (DCL1, DICER-LIKE 1), first to produce pre-miRNA and then to liberate miRNA-miRNA* duplex. DCL1 is associated with two partner proteins: HYPONASTIC LEAVES 1 (HYL1) containing dsRBDs and SERRATE (SE) containing a zinc-finger domain (Hiraguri *et al.*, 2005; Yang *et al.*, 2006). Unlike in animals, the 3' end nucleotides of plant miRNA/miRNA* duplexes are 2'-O-methylated by the methyltransferase HUA-ENHANCER 1 (HEN1) before loading to Argonaute (Yu *et al.*, 2005).

Plant *Arabidopsis* has 10 Argonaute proteins. Canonical miRNAs are loaded to AGO1. Unlike in animals, plant miRNAs are highly complementary to target RNAs through their entire length and the high degree of complementarity is required for efficient target slicing. Plant miRISCs suppress target RNAs mainly by cleaving them, although they can induce translational repression as well.

Mutations in the miRNA and the Pathway Genes Cause Human Diseases

Since miRNAs are important for normal functioning of cells, dysregulation of miRNAs and the miRNA pathway are associated with various human diseases.

Mutations in the miRNA Pathway Genes Cause Diseases

Mutations in the Dicer gene are associated with tumorigenesis such as pleuropulmonary blastoma, Sertoli-Leydig cell tumor, multinodular goiter, and embryonal rhabdomyosarcoma (Hill *et al.*, 2009; Sabbaghian *et al.*, 2014). Mouse models suggest that Dicer may function as a haplo-insufficient tumor suppressor; a gene product whose normal function is to inhibit or control cell division in which one normal gene copy alone cannot produce enough product to prevent tumor formation. Furthermore, Dicer mutation is associated with age-related macular degeneration, in which toxic Alu RNA is no longer degraded by Dicer and thus accumulates (Kaneko *et al.*, 2011).

Some particular SNP types in the Exportin-5 and Drosha genes are suggested to be linked with cancer progression (Ye *et al.*, 2008; Wang *et al.*, 2010; Zhang *et al.*, 2010). Somatic mutations were found in the TRBP gene in colorectal and endometrial tumors and in gastric cancer cell lines and in the AGO2 gene in colorectal and gastric cancers (Melo *et al.*, 2009; Kim *et al.*, 2010). Mutations in the PACT gene are associated with Dyt16, an autosomal recessive, young-onset dystonia-parkinsonism disorder (Camargos *et al.*, 2008; Seibler *et al.*, 2008).

DiGeorge syndrome is caused by the chromosomal deletion 22q11.2, a region that includes the DGCR8 gene locus (Shiohama *et al.*, 2003). Haploinsufficiency of DGCR8 in the mouse model for this deletion causes abnormal miRNA biogenesis in the brain and the behavioral and neurological defects associated with DiGeorge syndrome (Stark *et al.*, 2008; Fenelon *et al.*, 2011).

Mutations in the miRNA Genes Cause Diseases

Germline mutations in the miR-96, miR-184, and miR-17 approximately 92 genes cause hearing loss, keratoconus, and skeletal and growth defects, respectively (Mencia *et al.*, 2009; De Pontual *et al.*, 2011; Hughes *et al.*, 2011).

About half of the miRNA genes map to cancer associated loci or in fragile sites (Calin *et al.*, 2004). Overexpression, down regulation, and deletion of many kinds of miRNAs have been reported to impact oncogenesis. For example, mutations in miR-15a and miR-16-1 are linked with tumorigenesis (Zhang *et al.*, 2006; Mavrakis *et al.*, 2010).

There are extensive studies being conducted that attempt to use miRNA expression profile as a biomarker in diagnosis and prognosis of various diseases including cancers. In addition, inhibiting particular miRNA functions using oligonucleotide with complementary sequence to the miRNA can be used as therapeutic approach.

Nomenclature of miRNA

The prefix 'miR' is followed by a dash and a number (e.g., miR-8), the latter often indicating order of naming. Exceptions are the miRNAs discovered early in the research history, such as lin-4 and let-7, which are the first (in 1993 by the Victor Ambros group) and the second (in 2000 by the Gary Ruvkun group) miRNAs to be discovered, respectively (Lee *et al.*, 1993; Pasquinelli *et al.*, 2000; Reinhart *et al.*, 2000). miRNAs with nearly identical sequences except for one or two nucleotides are annotated with an additional lower case letter. For example, miR-20a would be closely related to miR-20b. let-7a, let-7b, let-7c, let-7d, let-7e, let-7f, let-7g, and let-7i are closely related each other. pre-miRNAs that lead to 100% identical mature miRNAs but that are located at different places in the genome are indicated with an additional dash-number suffix. For example, the pre-miRNAs pre-miR-7-1, pre-miR-7-2, and pre-miR-7-3 lead to an identical mature miRNA (miR-7) but are located in different regions of the genome. When two mature miRNAs originate from opposite arms of the same pre-miRNA, they are denoted with a -3p or -5p suffix. For example, miR-22-5p and miR-22-3p derive from the 5' arm and 3' arm,

respectively, of pre-miR-22. Alternatively, when relative expression levels of two miRNAs deriving from the opposite arms of a pre-miRNA are known, an asterisk (star) following the name indicates a miRNA expressed at low levels relative to the miRNA in the opposite arm of a hairpin. For example, miR-22 and miR-22* (miR-22 star) would share a pre-miRNA hairpin (pre-miR-22), but miR-22 is more abundant than miR-22* in the cell. Species of origin is designated with a three-letter prefix, for example, hsa-miR-22 is a human (*Homo sapiens*) miRNA and mmu-miR-22 is a mouse (*Mus musculus*) miRNA. hsa-pri-miR-22 and has-pre-miR-22 are human pri-miR-22 and pre-miR-22, respectively.

Glossary

3' compensatory binding Occurs when insufficient 5' seed pairing in a miRNA is compensated by extensive 3' end pairing.

Kindred A group of related individuals.

Lac repressor A DNA-binding protein that inhibits the expression of genes coding for proteins involved in the metabolism of lactose in bacteria.

Single nucleotide polymorphism A single nucleotide (A, T, C, G) variation in the DNA sequence.

Introduction to Noncoding RNAs

Less than 2% of our genome codes for protein-coding genes. However, it has become apparent in recent years that up to 90% of our genome is transcribed in one form or another. In addition to approximately 21 000 protein-coding genes, current estimates suggest that the human genome includes 9000 small RNAs, 10–32 000 long noncoding RNAs (lncRNAs) and 11 000 pseudogenes (Encode Project Consortium, 2012; Volders *et al.*, 2013). The list of small RNAs is long and includes; miRNAs (involved in posttranscriptional regulating of gene expression), transfer RNAs (involved in mRNA translation), small-interfering RNAs (implicated in posttranscriptional regulation of gene silencing), small nucleolar RNAs (involved in ribosomal RNA modifications), small nuclear RNAs (implicated in splicing), PIWI-interacting RNAs (involved in transposon repression), transcription initiation RNAs, promoter upstream transcripts, and promoter-associated small RNAs (all of which seem to be involved in regulation transcription) (Tay *et al.*, 2014). It is likely that this nonprotein coding portion of the genome contributed to our evolution. In yeast, the protein-coding portion of the genome accounts for most of the genome, while as noted above, in mammals the protein-coding portion accounts for only 2% (Encode Project Consortium, 2012).

Introduction to miRNAs: Discovery, Biogenesis, and Nomenclature

Discovery

The most studied class of small noncoding RNAs is microRNAs or miRNAs, single-stranded mRNA sequences of 19–25 nucleotides in length (Bartel, 2005). Their primary function is to negatively mediate posttranscriptional regulation of mRNA (Wakiyama *et al.*, 2007; Bartel, 2004), although there are some reports showing upregulation of a target gene (Vasudevan *et al.*, 2007; Orom *et al.*, 2008). The first miRNA was discovered in 1993 by Victor Ambros' laboratory (Lee *et al.*, 1993). While studying *Caenorhabditis elegans* development, they discovered that a small RNA encoded by the *lin-4* gene regulated *lin-14* protein abundance. At the same time, Gary Ruvkun's laboratory identified the first miRNA-target gene, also in *C. elegans* (Wightman *et al.*, 1993). Combined, these two reports uncovered a novel mechanism of posttranscriptional

gene regulation, and it was not until 7 years later that the second miRNA, *let-7*, was discovered (Reinhart *et al.*, 2000). In 2001, the Bartel, Tuschl, and Ambros laboratories independently identified additional miRNAs and miRNA conservation across species started to emerge (Lagos-Quintana *et al.*, 2001; Lau *et al.*, 2001; Lee and Ambros, 2001). Indeed, >50% of miRNAs found in *C. elegans* have homologs in humans, and although there are some examples of primate specific miRNAs (Robles and Harris, 2013; Bentwich *et al.*, 2005; Perdomo *et al.*, 2013), the vast majority of a miRNA's family tree is traced back as far as plants (Bartel, 2005). Although the discovery of the actual genes was novel, their mechanism of action, i.e., of acting in a posttranscriptional manner on a mRNA strand, had been postulated by Jacob and Monod in 'model II' as far back as 1961 when they were studying the mechanisms of the lac repressor (Jacob and Monod, 1961).

miRNA genes are smaller than protein-coding genes. They can be found within genes or as independent genes in intergenic regions. Intergenic miRNAs often lie in an antisense orientation to neighboring genes, which suggests that they have independent transcriptional control (for example, miR-375). For miRNAs that lie within genes, the host gene can be either protein-coding (e.g., miR-101-2) or nonprotein-coding (e.g., *let-7c*). Intragenic miRNAs are often co-transcribed with the host gene and tend to be located within introns (e.g., miR-608); miRNAs located within introns are also called miRtrons. However, some miRNAs can overlap with exons (e.g., miR-711) (He *et al.*, 2012; Rodriguez *et al.*, 2004) and miRBase currently counts 89 exonic miRNAs (Marsico *et al.*, 2013). More than 50% of miRNAs exist within clusters, the so-called *cistronic* miRNAs (they can be bi- or poly-cistronic) (Tanzer and Stadler, 2004). One of the main examples of a *cistronic* miRNA is the miR-17–92 cluster. It is transcribed as a single sequence and subsequently processed into 6 individual miRNAs. A useful website has been developed that lists miRNAs according to which area of the genome/types of genes they reside in (see Integratome TIME in Relevant Websites) (Godnic *et al.*, 2013).

Biogenesis

Both intergenic and within gene (intragenic) miRNAs are transcribed by RNA polymerase II (Lee *et al.*, 2004), have a 5' cap and 3' poly (A) tail (Cai *et al.*, 2004). A small number of human miRNAs, approximately 50, lie within Alu repeat

regions (e.g., the chromosome 19 miRNA cluster [C19MC]) (Bentwich *et al.*, 2005). Alu transcription is mediated by RNA polymerase III and miRNA genes within repetitive elements are also transcribed by RNA polymerase III (Borchert *et al.*, 2006). Intergenic miRNAs can be several kilobases in length, something that makes the annotation of their promoters difficult. However, several online bioinformatics tools have been developed to overcome this (Megraw *et al.*, 2009), including ARTS (Sonnenburg *et al.*, 2006) and CoreBoost_HM (Wang *et al.*, 2009). While intronic miRNAs in exons tend to be transcribed with the host gene, emerging evidence suggests that some intronic miRs have their own promoters (Monteys *et al.*, 2010; Oszolak *et al.*, 2008; Ladewig *et al.*, 2012) and interestingly, these promoters tend to lie within a different intron to the one in which the miRNA is located (Oszolak *et al.*, 2008). The role of these promoters is unclear, but a recently developed program that bioinformatically identifies promoters in intronic miRs could be used to further experimentally clarify the importance of such promoters (Marsico *et al.*, 2013). Interestingly, intragenic miRNAs that lie in exons are generally not predicted to have an independent promoter, suggesting that they may arise through splicing of the host gene.

The processing of intergenic and intragenic miRNA differs in some ways (Winter *et al.*, 2009) and not all components are fully understood. Following transcription of intergenic miRNAs into pri-miRNA sequences, the hairpin loops are recognized by DGCR8, which then associates with Drosha, an RNase III family member that cleaves the hairpin approximately 11 nucleotides from the base of the hairpin (Kim, 2005; Kim *et al.*, 2009). This new pre-miRNA has a two-nucleotide overhang at its 3' end; it also has 3' hydroxyl and 5' phosphate groups (it is usually 60–100 nucleotides in length). Intragenic miRNAs are often spliced directly from their host gene's mRNA transcript and bypass DGCR8 and Drosha processing, though for those with their own promoter a mechanism similar to intergenic miRNAs is likely to occur.

Pre-miRNA hairpins derived from either intergenic or intragenic regions are exported from the nucleus by Exportin-5/RAN-GTP – Exportin-5 recognizes the two-nucleotide overhang. In the cytoplasm, Dicer, TRBP, and Ago proteins bind to the hairpin and load it onto the RNA-induced silencing complex (RISC) where a mature miRNA duplex is formed by the RNase III action of Dicer. Each pre-miR produces two mature miRNA strands. In general, one of the strands is degraded and the other remains loaded in the RISC complex, ready for mRNA targeting (Lin *et al.*, 2005). The decision regarding which strand remains in the RISC complex seems to largely depend on thermodynamics.

When a miRNA finds its complimentary mRNA strand, Ago will either cleave the mRNA transcript (Lim *et al.*, 2005) or the complex will repress translation. The higher the degree of overlap between the miRNA sequence and the mRNA sequence to which it binds, the higher the likelihood that the sequence will be degraded (Bartel, 2004; Bartel, 2005). In plants, each miRNA normally targets a single mRNA and has very high sequence complementarity to its mRNA. Therefore miRNA-target binding in plants usually leads to cleavage of the mRNA strand via endonucleolytic activity. Recent work predicts that >60% of protein-coding genes are regulated by

miRNAs (Friedman *et al.*, 2009) and mRNA transcripts can have multiple miRNA binding sites within their 3'UTR (Hobert, 2004; Krek *et al.*, 2005; Hon and Zhang, 2007). Binding to an mRNA sequence by a miRNA is governed by a series of biochemical rules, though not all criteria are fully known. Current bioinformatics tools for predicting miRNA targets consider the degree of conservation, the 'seed' sequence (nucleotides 2–7 of the mature miRNA sequence), the number of sites within an mRNA target, and features of the surrounding mRNA sequence, such as secondary structure (Lewis *et al.*, 2003; Krek *et al.*, 2005). Common examples of bioinformatics tools that help to predict mRNA targets include TargetScan (Lewis *et al.*, 2003), miRanda (John *et al.*, 2004), rna22 (Loher and Rigoutsos, 2012), DIANA-microT (Margakakis *et al.*, 2011) and PicTar (Krek *et al.*, 2005). However, the gold standard approach for confirming miRNA targets remains empirical experimental testing.

The seed region is the primary sequence within the miRNA that confers specificity to a particular mRNA target; it can be considered analogous to that of consensus sequences in DNA that recognize transcription factors (Hobert, 2004). Although the binding between the seed region is (mostly) in perfect Watson–Crick complementarity, flanking regions do not have to bind with equal precision. However, studies show that key features of the transcript, including the exact configuration of mismatches in the mRNA sequences outside of the seed region, can influence the efficacy of translation repression (Aleman *et al.*, 2007; Grimson *et al.*, 2007). It should be noted that not all miRNA-mRNA binding takes place in the 3'UTR. Indeed, miRNAs have also been found to bind to coding regions (Xu *et al.*, 2009) as well as 5'UTRs (Orom *et al.*, 2008; Place *et al.*, 2008); these binding patterns however appear to be less frequent than canonical 3'UTR binding, but they are biologically pertinent. For example, binding of miR-10a to the 5'UTR of several ribosomal proteins actually enhances their translation (Orom *et al.*, 2008), while miR-122 binds to the 5' UTR of the hepatitis C RNA and promotes viral accumulation (Jopling *et al.*, 2005). A recent analysis of miRNA binding sites located within coding sequences suggests that they function to effectively inhibit translation, rather than mediate mRNA degradation (Xu *et al.*, 2009; Hausser *et al.*, 2013).

Nomenclature

The nomenclature of miRNAs has evolved since their discovery in 1993 (Griffiths-Jones *et al.*, 2006). They are initially annotated by species and start with a three or four letter prefix (for example, hsa for *Homo sapiens*) that is followed by a dash (for example, hsa-miR-145). An un-capitalized r refers to the pre-miRNA (for example mir-9), while the capitalized R refers to the mature miRNA (for example miR-9). Some miRNAs are annotated with a lower case letter, such as a or b (for example, miR-34a, miR-34b and miR-34c). This designation is used for miRNAs whose sequences are almost identical except for one or two nucleotides. Human miRNAs also have paralogs, likely to have emerged through gene duplication events. These miRNAs are annotated by a dash followed by a number (e.g., miR-29b-1 and miR-29b-2). As mentioned, a single pre-miRNA duplex will lead to 2 mature miRNA strands. These are annotated with a 5p or 3p, depending on which arm of the

hairpin the miRNA arose from. In the past, these sequences were designated with *, with the * assigned to the least thermodynamically stable, and therefore least abundant, transcript. In the past, the 5p strand was oft referred to as the guide strand, while the 3p strand was called the passenger strand. When referring to a miRNA gene, the consensus is similar to that of protein-coding genes, where italics are used (i.e., *hsa-mir-21*).

The latest release of the miRBase database in 2013 (V20) cataloged 1872 precursor miRNA sequences and 2578 mature sequences in humans. In recent times, miRBase has started annotating 'high confidence' miRNAs based on the rise in deposition of next generation sequencing reads (Kozomara and Griffiths-Jones, 2014). In general, their criteria for calling a miRNA sequence as a *bone fide* transcript is based on having reads that map to both mature sequences of a mature miRNA duplex, presence of 2 nucleotide 3' overhangs (a remnant of Drosha activity) and relatively consistent 5' ends. Currently, only 20% of miRNAs are classified as high confidence in *Homo Sapiens* (Kozomara and Griffiths-Jones, 2014).

miRNAs and Cancer

Given their key role in acting as a rheostat for protein output, it is not surprising that miRNAs have been linked to the etiology, progression and prognosis of cancer (Di Leva *et al.*, 2014). The first evidence that miRNAs were connected to cancer came from the laboratory of Carlo Croce in 2002 where he, George Calin and their colleagues were studying Chr13q14, a region that is frequently deleted in chronic lymphocytic leukemia (CLL). They long suspected the presence of a tumor suppressor in the region but detailed genetic analyses failed to identify any causal (classical) genes. And so it was that two miRNAs, *mir-15* and *mir-16-1*, were identified and demonstrated to function as tumor suppressors (Calin *et al.*, 2002). Since then, studies have shown that expression of miRNAs are deregulated in almost every human cancer studied (Calin and Croce, 2006; Lu *et al.*, 2005; Volinia *et al.*, 2006); this deregulation could be an early event in the carcinogenesis process and mediate the effect of carcinogenic environmental exposures (Schembri *et al.*, 2009). miRNAs can also define specific histological subtypes (Mathe *et al.*, 2009; Yanaihara *et al.*, 2006; Landi *et al.*, 2010) and are expressed in tissue-specific patterns (Lagos-Quintana *et al.*, 2002). miR-124, for example, is predominantly expressed in the brain where it mediates neuronal differentiation (Makeyev *et al.*, 2007; Lagos-Quintana *et al.*, 2002), while miR-122 is mainly found in the liver where it can promote viral accumulation (Lagos-Quintana *et al.*, 2002; Jopling *et al.*, 2005). In addition, approximately 50% of all annotated human miRNA genes are located in fragile sites or areas of the genome that are associated with cancer (Calin *et al.*, 2002, 2004; Sevignani *et al.*, 2007).

Etiology

When Croce and colleagues discovered miR-15 and miR-16-1, they also discovered the first inherited mutation in a miRNA. A single nucleotide polymorphism (SNP) was found within *pri-mir-16-1* in a kindred with familial CLL (Calin *et al.*, 2005). This SNP was functional and led to decreased levels of miR-16-

1, most likely due to disruption of pri-pre processing. Interestingly, the same germ line mutation is found in New Zealand black mice that naturally develop CLL-like disease (Raveche *et al.*, 2007). Since then, SNPs in *mir-196a-2* (rs11614913), *mir-146a* (rs2910164) and others have been associated with risk of cancer in multiple studies (Wang *et al.*, 2014; Chen *et al.*, 2013; Zhang *et al.*, 2012; Jazdzewski *et al.*, 2008, 2009). Sequencing has shown that SNPs in miRNA genes, and specifically in miRNA seed regions, are rare (Saunders *et al.*, 2007; Chen and Rajewsky, 2006) and, owing to their conservation, any changes in a miRNA sequence are likely to be functional. Most changes will affect biogenesis and processing (as in the case of miR-16-1), or alter targeting (as in the case of miR-146a). rs2910164 in miR-146a was originally found to be associated with risk of papillary thyroid carcinoma – it was an usual case though, as the heterozygote genotype (GC) was associated with increased risk of cancer, rather than either the wild-type (CC) or homozygous variant (CC) genotypes. This phenomenon, called over-dominance (Parsons and Bodmer, 1961), is rare in genetic association studies but there was a novel biological reasoning behind it that is somewhat specific to the biology of miRNAs. As each pre-miR strand generates two mature miRNAs, when the genotype is homozygous for either the G (ancestral) or C allele (derived allele), there are two possible mature stands that are produced from the mother and father's copy of chromosome 5. However, if someone carries a G allele from their mother and the C allele from their father, then there are now three potential mature miRNA produced. Jazdzewski and colleagues found that these strands had different mRNA targets and that this effectively contributed to an increased risk of cancer (Jazdzewski *et al.*, 2008, 2009).

SNPs in the 3' UTR of a gene may create, as well as destroy, a miRNA binding site (Ryan *et al.*, 2010). Abelson *et al.* (2005) elegantly depicted the first demonstration of a 3' UTR miRNA-modulating SNP in 2005, which found that a mutation in the miR-189 binding site of *SLITRK1* was associated with Tourette's syndrome. We now know that disruption of miRNA-dependent regulation by SNPs in the miRNA binding site of target mRNAs is a *bona fide* mechanism for altered gene expression in cancer. In 2005 Frank Slack's laboratory was the first to show that the miRNA let-7 binds to the 3' UTR of KRAS and regulates its expression (Johnson *et al.*, 2005). Subsequently, a novel SNP within a let-7 binding site was discovered and found to be associated with a 2.3 fold increased risk of lung cancer among moderate smokers (Chin *et al.*, 2008). This SNP has also been associated with ovarian (Pharoah *et al.*, 2011), oral (Christensen *et al.*, 2009) and colorectal cancer outcome (Ryan *et al.*, 2012b; Ruzzo *et al.*, 2011; Smits *et al.*, 2011). There are many other examples of 3'UTR SNPs associated with risk of cancer, many of which have been shown to be functional (Zanetti *et al.*, 2012). Some data also suggests that SNPs in the miRNA processing machinery are linked to the etiology of cancer (Ye *et al.*, 2008; Clague *et al.*, 2010; Yang *et al.*, 2008).

Predicting Prognosis and Response to Therapy

miRNAs are also associated with prognosis and response to therapy. miR-21 was initially shown to be associated with both

lung and colon cancer survival by the Harris laboratory (Schetter *et al.*, 2008; Yanaihara *et al.*, 2006). This work has since been replicated by many groups and indeed high miR-21 levels are associated with the prognosis of over 12 cancer types (Nair *et al.*, 2012; Fu *et al.*, 2011; Oue *et al.*, 2014; Mathe *et al.*, 2009; Landi *et al.*, 2010). Let-7 is downregulated in lung cancer, and this decreased expression is associated with poor prognosis (Takamizawa *et al.*, 2004; Yanaihara *et al.*, 2006). Some miRNA-related SNPs have been associated with prognosis (Zheng *et al.*, 2013; Ryan *et al.*, 2012a,b).

In tandem with predicting prognosis, an important part of the clinical management of cancer patients is knowing which therapy a patient is most likely to respond to. There has been considerable success in breast and lung cancer in using the molecular features of a tumor to guide and predict response to therapy (estrogen receptor positivity for TamoxifenTM response, HER-2 positivity for Herceptin[®] response, EGFR-mutation positivity for Erlotinib response and the *EML4-ALK* fusion gene positivity for guiding response to Crizotinib). Given the documented role of miRNAs in cancer (discussed below), there is an increasing recognition that miRNA patterns could also predict response to treatment. High levels of miR-21, for example, have been associated with resistance to chemotherapy in several types of cancer (Zhang *et al.*, 2011; Kurashige *et al.*, 2012; Wang *et al.*, 2013; Valeri *et al.*, 2010; Tomimaru *et al.*, 2010; Oue *et al.*, 2014). This correlation is most likely derived from (1) its upregulation in the cancer versus normal tissue, and (2) its role as a negative regulator of several cell death genes. Studies have also documented a decrease in circulating miRNAs in the weeks following surgery or treatment for cancer (Le *et al.*, 2012; Jung *et al.*, 2012; Zheng *et al.*, 2011; Sun *et al.*, 2012; Schwarzenbach *et al.*, 2014), suggesting that miRNAs could also be used as noninvasive predictors of tumor recurrence (Ohyashiki *et al.*, 2011; Schwarzenbach *et al.*, 2014).

The Role of miRNAs in Carcinogenesis

While dysregulation of miRNA expression in cancer could reflect a consequence rather than a cause of cancer, multiple lines of evidence suggest that miRNAs are indeed directly involved in the process of carcinogenesis. Examples of miRNAs acting as oncogenes (the so-called oncomiRs), tumor repressors, or both, have been described. For example, transgenic expression of miR-155 (Costinean *et al.*, 2006) or miR-21 (Medina *et al.*, 2010) leads to malignancy. Also, the aforementioned miR-17–92 cluster accelerates cancer induced by c-myc in mouse models of B-cell lymphoma (He *et al.*, 2005); transgenic mice expressing the miR-17–92 cluster developed tumors twice as early as tumors without the cistronic cluster of miRNAs. In addition to being involved in CLL, the miR-15 and miR-16-1 cluster is also lost in prostate cancer and multiple myeloma (Ambs *et al.*, 2008; Rocco *et al.*, 2009), while attempts at restoring the cluster actually sensitized cisplatin resistant cells (Pouliot *et al.*, 2012). Conversely, systemic delivery of tumor suppressive miRNAs, including let-7 and miR-34, inhibits tumor progression *in vivo* (Kota *et al.*, 2009; Pramanik *et al.*, 2011; Trang *et al.*, 2010; Wiggins *et al.*, 2010). Indeed, in 2013, the first clinical trial involving a human miRNA was initiated by Mirna Therapeutics, Inc. The Phase I

trial is being conducted in patients with un-resectable primary liver cancer or metastatic cancer with liver involvement.

As mentioned, the same miRNA can function as both an oncogene and tumor suppressor – depending on the tissue in which is expressed. Thus one cannot automatically infer a function from one tissue type to another. For example, miR-221 and miR-222 inhibit the growth of erythroblastic leukemia by targeting the oncogene KIT (Felli *et al.*, 2005). However, in models of liver cancer and hepatocellular carcinoma, miR-221 and miR-222 target PTEN and TIMP3 and induce TRAIL resistance, thereby acting as an oncomiR (Garofalo *et al.*, 2009). Thus, experimental evidence will always be needed to verify the cancer promoting or inhibiting effects of a miRNA.

miRNAs may also be related to cancer stem cell biology. The cancer stem hypothesis posits that a sub-fraction of cancer stem cells is responsible for the initiation, maintenance and progression of cancer. Central to this hypothesis is the stem cell characteristics that these tumor-initiating cells possess (Bonnet and Dick, 1997). Dysregulation of miRNAs has been found in cancer stem cells compared with healthy tissue. The miR-200 family, for example, is decreased in breast cancer stem cells (Shimono *et al.*, 2009; Polytaichou *et al.*, 2012). These miRNAs play a key role in suppressing epithelial-to-mesenchymal transition, migration, invasion and metastasis (Mongroo and Rustgi, 2010) through targets such as ZEB1 and ZEB2. An *in vitro* screen of miRNAs that could inhibit the growth of breast cancer stem cells also identified miR-15 and miR-16-1, miR-103 and miR-107, miR-145, miR-335, and miR-128b. In hepatocellular carcinoma, cancer stem cells defined by EpCAM expression express high levels of miR-181 family members (Ji *et al.*, 2009). Ji and colleagues found that inhibiting miR-181 led to a reduction in the cancer stem cell population and tumor-initiating ability, suggesting that targeting miRNAs could be an effective clinical strategy.

miRNAs as a Target for Therapy

As mentioned, cancers of nearly all kinds display global changes in miRNA expression. It is likely that some of these altered miRNAs are consequences, rather than causes, of carcinogenesis and it has been difficult to identify the true miRNA drivers. However, a few key oncogenic and tumor suppressor miRNAs have emerged and as stated above, a clinical trial involving a miRNA has already been initiated. The miR-34 family of genes, which includes miR-34a, miR-34b and miR-34c, are directly regulated by p53. They are classified as tumor suppressors, can be hyper-methylated in cancer (Gallardo *et al.*, 2009) and are located in fragile sites (Calin *et al.*, 2004). miR-34 antagonizes pathways that are essential for cancer cell viability as well as cancer stemness, metastasis, and chemoresistance. The results of this clinical trial will be eagerly awaited.

The goal of miRNA replacement therapy, for example, with miRNAs like miR-34, is to restore a loss of normal function (Bader *et al.*, 2010), but issues with RISC saturation have already emerged (Grimm *et al.*, 2006), as has the potential of inducing unwanted side-effects when new miRNAs are introduced into a cell. Encouragingly, however, preliminary animal models suggest that these side effects could be minimal (Kota *et al.*, 2009; Wiggins *et al.*, 2010).

Inhibiting oncogenic miRNAs can be initiated by several strategies, including anti-miRs, locked nucleic acids (LNAs), and antagomiRs, developed by Tuschl and colleagues. miRNA antagonists are single-stranded RNA molecules, approximately 21–23 nt long, that act through complementary base-pairing with miRNAs (Krutzfeldt *et al.*, 2007). To increase the pharmacological inhibition of target miRNAs, various chemical modifications are used to enhance binding affinity, confer nuclease resistance, and facilitate cellular uptake. These include adding phosphorothioate backbones, 2'sugar modifications such as 2'-O-methyl (2'-Ome) (the so-called antagomiRs) and LNAs (Krutzfeldt *et al.*, 2005; Levin, 1999). *In vivo* experiments with an antagomiR targeting miR-122 have demonstrated effective inhibition of miR-122 and decreases in plasma cholesterol levels (Esau *et al.*, 2006), while an LNA-modified form of a miR-122 anti-miR led to long-lasting suppression of hepatitis C virus in primates (Lanford *et al.*, 2010).

miRNAs are found in several biological fluids – not just tissue. Indeed, the discovery of miRNAs in the circulation led to the identification of a new function for miRNAs, i.e., as activators or ligands for Toll-like receptors (TLR) (Fabbri *et al.*, 2012; He *et al.*, 2014). Fabbri and colleagues found that miR-21 excreted from lung cancer cells in exosomes was taken up by macrophages wherein the miRNA bound to, and activated, TLR8, leading to the production of pro-inflammatory cytokines. Given that miRNAs are over-expressed and decreased in many forms of human cancer, this raises the possibility that miRNAs could be used as a form of 'liquid biopsy' and be useful in cancer diagnosis and predicting outcome (Cortez *et al.*, 2011). They are remarkably stable in these biospecimens, in large part due to their small size and protection from endogenous RNase activity (Mitchell *et al.*, 2008). In the circulation, cell-free miRNAs exist in 2 main forms – either bound to Ago2 or encapsulated within microvesicles, such as exosomes (Mitchell *et al.*, 2008). When trying to detect miRNAs in fluids such as serum or plasma, considerable attention needs to be paid to both sample preparation and RNA extraction – both of which have been shown to affect the endpoint of miRNA detection. Differential centrifugation will isolate different populations of cell-free miRNAs – centrifuging at >110 000 g, for example, will isolate exosomal miRNAs. Other factors to consider are the choice of serum versus plasma – hemolysis floods the circulating miRNA pool with myeloid-derived miRNAs, such as miR-223, miR-197, miR-594-3p, and let-7a, and conditions that lead to a fluctuation in blood cell levels can influence miRNA abundance levels by up to 50-fold (Pritchard *et al.*, 2012). RT-PCR and deep sequencing are the main methods used to identify circulating miRNAs at present. For a good review of this area see (Schwarzenbach *et al.*, 2014). Despite the challenges in identifying and isolating miRNAs in bodily fluids, some studies have shown significant associations with diagnosis and prognosis of cancer (Schwarzenbach *et al.*, 2014). However, robust and extensive validation of methods and results will be needed to verify these associations and move them into clinical use.

IsomiRs

Before their official annotation as 'isomiRs' by Morin *et al.* (2008), miRNA variants had been identified in cloning studies

but were ambiguously misclassified as putative experimental error (Ruby *et al.*, 2006; Landgraf *et al.*, 2007; Ebhardt *et al.*, 2009). Their discovery owes much to the acceleration in next generation sequencing technology and researchers are now confident that they are not due to RNA degradation during sample preparation for RNA sequencing (Bizuayehu *et al.*, 2012). miRbase records the most abundant miRNA sequence as the reference sequence. In recent years, it has started to include miRNA sequence heterogeneity as part of its database.

IsomiRs are formed via posttranscriptional editing. Four main forms of editing are known; 3' trimming, 5' trimming, 3' nucleotide addition (usually adenylation or uridylation) and internal nucleotide substitution. The latter two are less common than trimming events. The location of trimming variations suggests that they generally arise from variable cleavage sites for DROSHA and DICER1 in the hairpin (Lu *et al.*, 2009). Wyman and colleagues implicated the nucleotidyl transferases MTPAP, PAPD4, PAPD5, ZCCHC6, ZCCHC11, and TUT1 in 3' miRNA modification in human cells (Wyman *et al.*, 2011).

IsomiRs were initially described in plants and lower organisms (Morin *et al.*, 2008; Aravin and Tuschl, 2005). However, isomiRs are conserved from plants to humans (Wyman *et al.*, 2011). Recently, isomiRs have been detected in animals (Bizuayehu *et al.*, 2012) and *Drosophila melanogaster* (Fernandez-Valverde *et al.*, 2010). Furthermore, isomiRs have been described in human stem cells (Pantano *et al.*, 2010) and human brain tissue (Marti *et al.*, 2010). Although they are detected, a key question is whether they are biologically relevant. Recent work suggests that they are. For example, miR-282, and miR-312 have 3'adenosine additions during early development of *D. melanogaster*. These newly edited miRNAs show subsequent enrichment in target sites for developmental genes expressed during late embryogenesis, suggesting that non-DNA templated additions to a miRNA can strengthen miRNA-target gene interactions (Fernandez-Valverde *et al.*, 2010). The functionality of adenylation or uridylylation at the 3' end has been related to stability (Burroughs *et al.*, 2010). A recent study found that the addition of an adenine to miR-122 enhanced the stability of the miRNA, while plant miRNAs that end with an adenine have slower decay rates (Kai and Pasquinelli, 2010). The addition of uridines to the 3' end of miRNAs has been reported (Li *et al.*, 2005; Heo *et al.*, 2009; Heo *et al.*, 2008), but its significance is less understood. Some suggest that uridylation at the 3' end could mediate miRNA turnover or facilitate mRNA-miRNA binding in cases in which 3' compensatory binding is predominant. This addition may also function as a degradation signal, perhaps in a manner that is analogous to protein ubiquitylation (Li *et al.*, 2005).

miRNAs with 5' modifications are especially interesting as they will have a seed sequence that differs from the reference sequence, opening up the possibility that the isomiRs will have different pools of mRNA targets. Though rarer than 3' end modification events, modification at the 5' end of miRNAs has been observed in T cells (Wu *et al.*, 2007) and isomiRs of mir-142 are differentially expressed during antigen-induced T cell differentiation (Wu *et al.*, 2007). 5' end modifications are a conserved phenomenon (Wu *et al.*, 2007; Waidner *et al.*, 2009; Ruby *et al.*, 2006; Seitz *et al.*, 2008). An analysis of brain-derived miR-101 detected a 5' isomiR that was highly abundant, incorporated into RISC, and bound to miR-101 targets,

albeit with less efficiency than canonical miR-101 (Llorens *et al.*, 2013a). The identity of the 5' nucleotide directs miRNAs to Ago, though 3' end nucleotides could also have an effect. There are several members of the Ago family (Liu *et al.*, 2004), thus any changes in nucleotide identity could alter isoform-specific loading of miRNAs (Burroughs *et al.*, 2011; Juvvuna *et al.*, 2012).

Internal editing of mature miRNAs also occurs (Reid *et al.*, 2008), although there is a selection against nucleotide alterations in nucleotides 2–7 (seed) and 10–15 (cleavage and anchor sites). Internal editing could also affect stability and the pool of mRNA targets. Work suggests that this RNA-editing can alter the specificity by which miRNAs associate with Ago proteins (Landgraf *et al.*, 2007).

In a recent analysis of miRNAs from healthy individuals and patients with Huntington disease, 80–90% of small RNAs had some form of editing. Most of this editing occurred at the 3' end, and was in the form of trimming or nucleotide additions (Marti *et al.*, 2010). Differential expression of isomiRs has also been identified during differentiation (Wyman *et al.*, 2011). Strikingly, expression of isomiRs varied between healthy tissue and samples from patients with Huntington disease (Marti *et al.*, 2010). IsomiRs have also been implicated in cancer. In a mouse model of leukemia, several isomiRs were differentially expressed between healthy and diseased cells (Kuchenbauer *et al.*, 2008). For example, let-7a-5p had 78 sequences derived from various combinations of 5' and 3' modification: some of these sequences had counts greater than 4000 and were therefore highly expressed. The miR-181 family of putative tumor suppressors and miR-21, an oncomiR, also has a remarkable level of sequence variation. Several studies have shown differential expression of isomiRs in normal compared with cancer tissue (Li *et al.*, 2012; Llorens *et al.*, 2013b; Chan *et al.*, 2013). Although these variations have not been functionally interrogated in either normal or cancer biology, it is plausible that they are relevant to tumorigenesis and it is likely that studying and understanding miRNA editing will add greater understanding to both normal and cancer cell biology.

Other Forms of Noncoding RNAs and their Relevance to Cancer

ceRNAs

While it was first thought that miRNAs only bound to message RNA transcripts, it has become increasingly clear the much of the RNAome, including lncRNAs and pseudogenes, contains binding sites for miRNAs. This realization, and the possibility of cross talk regulation, led to the development of the term competing endogenous RNAs, or ceRNAs (Salmena *et al.*, 2011). ceRNAs may function as a decoy for miRNA binding. In T cells transformed with Herpesvirus saimiri, seven noncoding RNAs are produced that have binding sites for host miRNAs, including miR-27a. Binding between miR-27a with the viral noncoding RNAs leads to degradation of the miR-27a and thus downstream consequences for the targets of miR-27a. Such a cunning viral strategy illustrates a key example of how a noncoding RNA exerts a cross talk regulation of host-cell gene

expression via miRNAs (Cazalla *et al.*, 2010). In another example, binding of miRNAs to a PTEN pseudogene, PTENP1, regulates the effect of miRNAs by competing for their binding (Poliseno *et al.*, 2010).

eRNAs

Enhancers, genetic elements that regulate gene transcription upstream from the promoter region, were identified in 1981 by Schaffner and colleagues while studying the beta-globin gene (Banerji *et al.*, 1981). At the time, they were considered to be DNA elements and since their discovery, it has become clear that an enhancer can exist far from the gene it regulates. For example, in the case of sonic hedgehog its enhancer lies almost a megabase away (the enhancer lies in an 800-base pair region within intron 5 of the *Lmbr1* gene) (Lettice *et al.*, 2003). In 2010, Natoli and colleagues discovered that 70% of extragenic RNA polymerase II peaks were associated with enhancers (De Santa *et al.*, 2010). Michael Greenberg and colleagues subsequently found that enhancers activated by neuron depolarization were transcribed in multiple places throughout the genome and that expression of the enhancer RNAs (eRNA) correlated with mRNA of the nearest gene (Kim *et al.*, 2010). eRNAs can be transcribed both a single and bi-directional manner. Unidirectional transcription of enhancer regions usually generates long (4 kb) polyadenylated transcripts (Heintzman *et al.*, 2007), while those transcribed in a bi-directional manner are usually shorter (0.5–2 kb) and not polyadenylated (Koch *et al.*, 2011). It is not entirely clear whether expression of eRNAs in tandem with their mRNA target is a mark of active transcription, or whether it has a specific function, with some suggesting that eRNAs are indeed just a by-product of transcription. Whether or not it is a widespread phenomenon of all eRNAs, physiological functions have been noted for eRNAs. For example, Rosenfeld and colleagues found that when 17 β -estradiol is bound to its receptor in breast cancer cells (ER- α), an increase in eRNAs beside estrogen-regulated genes occurs. Removing the eRNAs abrogated their ability to increase gene expression (Li *et al.*, 2013). While more work is needed to understand whether eRNAs are broadly functional, their importance for regulating gene expression and potential contributions to disease (Lettice *et al.*, 2003) are established.

LncRNAs

LncRNAs can be between 200 nucleotides and 100 kilobases in length. One of the best known lncRNAs, XIST, was known and functionally characterized many years before lncRNAs were an official class of noncoding RNAs (Brockdorff *et al.*, 1992; Brockdorff *et al.*, 1991) (mouse XIST was discovered in 1991). XIST is a 15 kb length transcript and causes X-inactivation, a compensation mechanism developed in mammals to offset the unequal number of sex chromosomes in males and females. In female cells, XIST initially covers gene-rich islands on the X-chromosome before spreading to less gene dense regions (Simon *et al.*, 2013).

LncRNAs are primarily transcribed by RNA polymerase II though some cases of transcription by RNA polymerase III are described. (Bierhoff *et al.*, 2010). They are classified in terms of

their orientation and location relative to neighboring genes (Rinn and Chang, 2012). In addition to the scaffolding function as described for XIST, lncRNAs can also function as enhancers and decoys. Since their discovery as a class of noncoding RNAs, lncRNAs have undergone a few changes in nomenclature, but an official naming system has been established (Wright and Bruford, 2011). An in-depth discussion of lncRNAs is beyond the scope of this article, but it is important to mention that, as observed with miRNAs, deregulated lncRNA expression has been identified in a multitude of cancers (Tang *et al.*, 2013; Zhang *et al.*, 2009; Gutschner and Diederichs, 2012; Luo *et al.*, 2006; Kim *et al.*, 2013). The lncRNA MALAT-1 is associated with prognosis in lung cancer (Schmidt *et al.*, 2011). Recently, it was also identified as a target for miR-9 in an Ago2-dependent manner (Leucci *et al.*, 2013).

Transposons and piRNAs

A transposon, or transposable element, is a small piece of DNA that can insert itself into another part of the genome. They were discovered by Barbara McClintock in 1940s while she was studying corn and differing coloration patterns in kernels (McClintock, 1950). Transposons can travel or 'jump' to alternate regions of the genome, while in other cases they make copies of themselves and then 'paste' into new regions of the genome. In bacteria, for example, transposons often carry genes that allow these microorganisms to develop antibiotic resistance. Recently, The Cancer Genome Atlas (TCGA) identified transposons as a probable source of novel mutations across many tumor types. Specifically, almost 200 transposable element insertions were identified, 62 of which had 'jumped' to known tumor suppressors and often altered the expression of their new host gene (Lee *et al.*, 2012).

Small RNA-dependent silencing mechanisms have evolved to regulate the activity of transposable elements (Malone and Hannon, 2009). In *Drosophila*, for example, transposons are silenced by repeat associated siRNAs (rasiRNA) (Klattenhoff *et al.*, 2007). rasiRNAs are now called piRNAs (for piwi-interacting RNA) (Aravin and Tuschl, 2005). piRNAs are the biggest of the small noncoding RNAs at around 26–31 nucleotides in length – they are specifically expressed in the testis and thus are necessary for spermatogenesis (Malone and Hannon, 2009; Girard *et al.*, 2006). In mammals, the main activity of piRNAs is in transposon silencing, specifically during development of the embryo (Aravin and Tuschl, 2005). They are evolutionarily conserved (Wang and Reinke, 2008) and although their biogenesis is not very well understood, there is emerging evidence to suggest that piRNAs are involved in the epigenetic regulation of cancer (Yan *et al.*, 2014; Kwon *et al.*, 2014; Ferreira *et al.*, 2014; Mei *et al.*, 2013).

Summary

It is clear that the multitude of RNA species within our cells, and indeed, outside of our cells, have an intricate, elegant and complicated mode of communication (Tay *et al.*, 2014). Understanding the function and implications for disease of these small RNAs significantly lags behind their rate of

discovery. Furthermore, the emerging cross talk in the RNA world demonstrates an almost overwhelming level of complexity. Even among protein-coding genes, the mRNA transcripts that code for protein undergo significant shortening at the 3'UTR end in proliferating cells and in cancer cells, thereby creating a mechanism to escape miRNA-mediated repression and increases in the bioavailability of miRNAs (Sandberg *et al.*, 2008; Mayr and Bartel, 2009). Understanding the matrix of RNA communication will not only further our understanding of gene regulation, but given the knowledge developed over the last two decades on miRNAs and their contribution to health and disease, it is likely that such knowledge will further our understanding of diseases and inform new ways to both diagnose and treat disease more effectively.
